Diagnosis Algorithm

Assessment and diagnosis of T2DM

1. Asymptomatic patient

1.1 Does the patient have a BMI ≥ 25 kg/m² and one or more additional risk factors (see table)?

1.1.1 Yes

1.1.1.1 Symptomatic patient

…

1.2 No

1.2.1 Asymptomatic patients with no risk factors should not be screened for T2DM, regardless of age

1.3 Does the patient have increased cardiovascular risk (see table)?

1.3.1 No

1.3.1.1 Asymptomatic patients with no risk factors should not be screened for T2DM, regardless of age

1.3.2 Yes

1.3.2.1 Diagnostic testing for T2DM – A1c, OGTT or FPG

1.4 Yes

1.4.1 Diagnosis of prediabetes

• A1c between 5.7-6.4%
• FPG between 100-125 mg/dL
• OGTT between 140-199 mg/dL

1.5 Risk Factors Table

1.1 BMI ≥ 25 kg/m² and one or more of the following risk factors:
• High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
• Women who have delivered a baby weighing > 9 lb or were diagnosed with GDM
• Women with polycystic ovarian syndrome
• “Prediabetes” as defined by IFG, IGT or A1c on previous testing
• Other clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)
• History of first degree relative with T2DM

1.2 Cardiovascular Risk Factors

• Established ASCVD
• Hypertension (blood pressure ≥ 140/90 mmHg or on hypertension therapy)
• HDL cholesterol < 35 mg/dL
• Triglyceride level > 250 mg/dL
• LDL cholesterol > 70 and calculated 10 year cardiovascular event risk > 7.5 or on lipid lowering therapy

1.6 Treatment to prevent or delay the progression to T2DM

Shared decision-making

A recommendation has been made and should be utilized; the benefit outweighs the harms for most patients.

A recommendation has been made and may be utilized; the benefit is felt to potentially outweigh the harms for most patients.

A recommendation against has been made; the harms outweigh the benefits for most patients.

Management Algorithm

Patient diagnosed with T2DM

Does the patient need inpatient diabetes management?

Personalize goals to achieve glycemic control with a hemoglobin A1c in the range of < 7 or 8% based on the risks and benefits for each patient

Recommend education and self-management, as appropriate

5.1 Nutrition therapy
5.2 Physical activity
5.3 Weight management
5.4 Bariatric surgery*
5.5 General diabetes self-management education
5.6 Foot care education
5.7 Tobacco cessation

* Bariatric surgery may be considered but is not a treatment strategy for all patients

Initiate metformin as first-line pharmacotherapy for patients with T2DM, unless medically inappropriate

Review all cardiovascular risk factors and assess the need for the following management:

7.1 Antihypertensive therapy
7.2, 7.3 Statin therapy
7.4 Aspirin therapy

Review all cardiovascular risk factors and assess the need for the following management:

7.1 Antihypertensive therapy
7.2, 7.3 Statin therapy
7.4 Aspirin therapy

See Cardiovascular Risk Management algorithm

Are treatment goals met?

no

Modify treatment; if applicable use appropriate related guideline

- Assess patient adherence/capacity
- Evaluate for depression
- Insulin management

Ongoing management and follow-up

Maintain treatment goals and address complications

yes

Inpatient diabetes management

Shared decision-making

Text in blue in this algorithm indicates a linked corresponding annotation.
Cardiovascular Risk Management Algorithm

| Review all cardiovascular risk factors and assess the need for the following management: |
| 7.1 Antihypertensive therapy |
| 7.2, 7.3 Statin therapy |
| 7.4 Aspirin therapy |

Antihypertensive therapy

- Blood pressure > 140/90 mmHg?
  - yes
    - Initiate antihypertensive medication and treat to a goal of < 140/90
      - For additional information, refer to the ICSI Diagnosis and Management of Hypertension guideline
  - no
    - no

- Patient > 40 years old?
  - yes
    - Initiate a high-intensity statin therapy
      - For additional information, refer to the ICSI Lipid Management in Adults guideline
    - no
      - Shared decision-making

- Established ASCVD or LDL > 190 mg/dL?
  - yes
    - Initiate high-intensity statin therapy
  - no
    - Shared decision-making

Statin therapy

- 10-year ASCVD risk ≥ 7.5%?
  - yes
    - Initiate aspirin therapy for secondary prevention
  - no
    - LDL ≥ 70 mg/dL and < 75 years old?
      - yes
        - Consider aspirin therapy for primary prevention
      - no
        - Assess for other cardiovascular risk factors and return to the Management algorithm

Aspirin therapy

- Established ASCVD?
  - yes
    - Initiate aspirin therapy for secondary prevention
  - no
    - Shared decision-making

Assess for other cardiovascular risk factors and return to the Management algorithm

Text in blue in this algorithm indicates a linked corresponding annotation.

Shared decision-making with a full discussion of the risks and benefits of treatment and consideration of patient values and preferences.

Evidence Grading

Literature Search

This guideline is based on a systematic evidence review evaluating literature published on type 2 diabetes mellitus (T2DM). The literature search was divided into two stages to identify systematic reviews, (stage I) and randomized controlled trials, meta-analysis and other literature (stage II). Literature search terms used for this revision are below and include literature from January 1, 2004, through May 31, 2014. Hand searching of identified articles and work group submission was also undertaken.

The databases searched included PubMed and Cochrane. The search was limited to only studies in the English language. The following searches were performed and utilized in this document in regards to T2DM: screening, diagnosis, diagnostic testing, risk factors, bariatric surgery, blood pressure, lipid management, insulin, nutrition therapy, glycemic control, weight loss, metformin, self-management and education.

GRADE Methodology

Following a review of several evidence rating and recommendation writing systems, ICSI has made a decision to adopt to the Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology.

GRADE has advantages over other systems including the previous system used by ICSI. Advantages include:

• Developed by a widely representative group of international guideline developers
• Explicit and comprehensive criteria for downgrading and upgrading quality of evidence ratings
• Clear separation between quality of evidence and strength of recommendations that includes a transparent process of moving from evidence evaluation to recommendations
• Clear, pragmatic interpretations of strong versus weak recommendations for clinicians, patients and policy-makers
• Explicit acknowledgement of values and preferences and
• Explicit evaluation of the importance of outcomes of alternative management strategies

Return to Table of Contents
Foreword

Introduction

Diabetes is a chronic disease, that afflicts approximately 26.9% of U.S. residents aged 65 years and older. 1.9 million are diagnosed with diabetes every year, and an additional 7.0 million go undiagnosed and untreated (Centers for Disease Control, 2011). More than 1 in 5 health care dollars in the U.S. goes to the care of people with diagnosed diabetes, costing $245 billion dollars annually (American Diabetes Association, 2012).

Appropriate medication management targeting glycemic control, hypertension, and lipid management is important for reducing morbidity and mortality, and improving long-term quality of life for patients diagnosed with type 2 diabetes mellitus (T2DM). Lifestyle changes such as nutrition therapy, weight loss, increased exercise, and appropriate education and self-management strategies are pivotal to improved outcomes. Inadequate access to care for chronic disease management as well as the cost of medication can contribute to poor control of T2DM and associated cardiovascular risk factors.

In the current iteration of this guideline, we have focused on the importance of appropriate identification and diagnosis, followed by effective approaches to lifestyle management and pharmacologic therapy. Due to the high percentage of the U.S. population that is diagnosed with diabetes and the effect diabetes has on other comorbidities, appropriate management will improve the patient's experience of care and the health of the population, reducing office visits, emergency department visits, cardiovascular complications. Other related conditions will in turn reduce the total cost of care.

Return to Table of Contents

Scope and Target Population

This guideline provides a comprehensive approach to the diagnosis and management of T2DM in adults ages 18 and older. Management recommendations will include nutrition therapy, physical activity, self-management approaches and pharmacologic therapy, as well as the prevention and diagnosis of diabetes-associated complications and risk factors.

The management of gestational diabetes and T2DM in patients who are pregnant is excluded from the scope of this guideline. Oral agents do not have Food and Drug Administration approval for use in pregnancy. Additionally, the glycemia goals used are different in pregnancy and require more aggressive treatment. Please refer to the ICSI Routine Prenatal Care guideline for information relating to gestational diabetes and T2DM in patients who are pregnant.

The diagnosis and management of type 1 diabetes is not included in this guideline.

Return to Table of Contents
Aims

Note: a multifactorial intervention targeting hyperglycemia and cardiovascular risk factors in individuals with diabetes is most effective. Both individual measures of diabetes care, as well as comprehensive measures of performance on broader sets of measures, are recommended. A randomized controlled trial has shown a 50% reduction in major cardiovascular events through a multifactorial intervention targeting hyperglycemia, hypertension, dyslipidemia, microalbuminuria, aspirin and ACE inhibitor use in individuals with microalbuminuria (Gaede, 2003).

Goals for A1c, low-density lipoprotein and other diabetes measures should be personalized, and lower goals for A1c and low-density lipoprotein than those included here in the priority aims and measures may be clinically justified in some adults with T2DM. However, efforts to achieve A1c below 7% may increase risk of mortality, weight gain, hypoglycemia and other adverse effects in many patients with T2DM. Therefore, the aims and measures listed here are selected carefully in the interests of patient safety.

Outcome Measures

1. Diabetes Optimal Care: Increase the percentage of patients ages 18-75 years with T2DM mellitus who are optimally managed

2. Management of T2DM in high-risk patients (Trial measure): Decrease the percentage of adult patients ages 18-75 with T2DM mellitus with poorly controlled glucose and cardiovascular risk factors.

3. Lifestyle modification and nutrition therapy – increase the percentage of patients ages 18-75 years newly diagnosed with T2DM who are advised about lifestyle modification and nutrition therapy.

4. Medication Management – increase the percentage of patients with T2DM who are on appropriate medication management.

Clinical Highlights

• Education and self-management support is necessary for people with prediabetes and T2DM to manage his/her disease.

• Focus on cardiovascular risk reduction (blood pressure control, low-density lipoprotein cholesterol lipid control primarily with statin use, aspirin use and tobacco cessation).

• A1c levels should be individualized to the patient.

• Aggressive blood pressure control is just as important as glycemic control. Systolic blood pressure level should be the major factor for detection, evaluation and treatment of hypertension. The use of two or more blood pressure-lowering agents is often required to meet blood pressure goal.

• Prevent microvascular complications through annual or biannual eye exams, foot risk assessments and foot care counseling, and annual screening for proteinuria.

• Initial therapy with lifestyle treatment and metformin is advised, unless contraindicated.
Implementation Recommendation Highlights

The following system changes were identified by the guideline work group as key strategies for health care systems to incorporate in support of the implementation of this guideline.

The implementation of T2DM clinical guidelines at medical groups and clinics is a complex and challenging task. However, a number of key processes have been shown to accelerate effective clinical guideline implementation and care improvement (Sperl-Hillen, 2005). These overlapping care elements can be categorized at the medical group and clinician levels:

- **Essential elements at the medical group level:**
  - **Leadership.** Medical group leaders must communicate the need for change in clinical practice patterns and consistently identify improvement priorities.
  - **Resources.** Resources adequate to the task at hand will be needed to assure the success of a change effort. Resources may include staff time, money and provision of tools (such as electronic medical records) to support care improvement.
  - **Select specific improvement goals and measures.** For most chronic diseases, including diabetes, the most efficient improvement strategy is to focus on a limited number of specific improvement goals. These may be based on observed gaps in care, potential clinical impact, cost considerations or other criteria (O'Connor, 2005a). In T2DM, focusing on glycemic control, lipid control and blood pressure control is a strategy that has been shown to be effective in preventing up to 53% of heart attacks and strokes, the leading drivers of excess mortality and costs in adults with diabetes (Gaede, 2003).
  - **Accountability.** Accountability within the medical group is a management responsibility, but external accountability may also play an important enhancing role to motivate sustained efforts to implement guidelines and improve care. Examples of external accountability include participation in shared learning activities or public reporting of results (such as in pay-for-performance or the Minnesota Community Measures Project).
  - **Prepared practice teams.** The medical group may need to foster the development of prepared practice teams that are designed to meet the many challenges of delivering high-quality chronic disease care.

- **Essential elements at the clinic level:**
  - **Develop "smart" patient registries.** These are registries that are designed to identify, automatically monitor, and prioritize patients with diabetes based on their risk, current level of control, and possibly patient readiness-to-change.
  - **Assure "value-added" visits.** These are office visits or other patient encounters (by phone, e-mail, etc.) that include intensification of treatment if the patient has not yet reached his/her evidence-based clinical goals. Failure of clinicians and patients to intensify treatment when indicated (referred to as "clinical inertia") is a key obstacle to better diabetes care (O'Connor, 2005a; O'Connor, 2005b; O'Connor, 2003). Previsit planning and best practice prompts may help to increase the efficiency of patient visits and remind clinicians of needed tests and care.
  - **Develop "active outreach."** These are strategies to reach patients with chronic disease who have not returned for follow-up or for other selected elements of care. Outreach strategies that enhance the likeliness of a future provider encounter that addresses one of the barriers to patient activation (discussed below) may be more effective. Simple reporting of lab test results or care suggestions through the mail may be ineffective at addressing these barriers.
Emphasize "patient activation" strategies. These may include diabetes education and other actions designed to sustain engagement of patients with his/her diabetes care. Many patients with diabetes either (a) do not really believe they have diabetes, or (b) do not really believe that diabetes is a serious disease, or (c) lack motivation for behavioral change, or (d) do not believe that recommended treatments will make a difference to their own outcomes. For care to be effective, these issues must be addressed for many patients (O'Connor, 1997).

Algorithm Annotations

Diagnosis Algorithm Annotations

1. Assessment and Diagnosis of T2DM

1.1 BMI and Associated Risk Factors of T2DM

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A clinician may test asymptomatic patients for T2DM when the patient has a BMI ≥ to 25 kg/m² and has one or more additional risk factors (see below), regardless of age. | Quality of Evidence: Low  
Strength of Recommendation: Weak |
| • High-risk race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)  
• Women who have delivered a baby weighing > 9 lb. or were diagnosed with GDM  
• Women with polycystic ovarian syndrome  
• “Prediabetes” as defined by IFG, IGT or A1c on previous testing  
• Other clinical conditions associated with insulin resistance (e.g., severe obesity, acanthosis nigricans)  
• History of first-degree relative with T2DM | |

Benefits:  
Patients can develop T2DM without symptoms, and early detection of diabetes allows for earlier implementation of lifestyle modifications and glucose control, and has a legacy effect that can reduce or prevent complications including retinopathy, neuropathy, nephropathy, peripheral vascular disease, and microvascular and cardiovascular disease. Targeted testing for patients of any age who are overweight or obese and have additional risk factors has shown to be cost effective.

Harms:  
It is unclear for patients with prediabetes that there is a full understanding of which patients will progress to T2DM. Some patients may have increased testing and treatment without benefit, and having the diagnosis of diabetes could potentially have negative psychosocial and economic ramifications for individuals.

Benefits-Harms Assessment:  
Diabetes screening is potentially costly and has not been proven to result in improved patient outcomes. However, the condition is common, serious, and a cause of serious microvascular and macrovascular health complications. Selective testing of high-risk individuals can reduce the costs compared to universal testing. There are no significant harms to the health of individuals who undergo testing.

1.2 Cardiovascular Risk

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A clinician may screen asymptomatic patients for T2DM who have increased cardiovascular risk (see below), regardless of age. | Quality of Evidence: Low  
Strength of Recommendation: Weak |
| • Established ASCVD  
• Hypertension (blood pressure ≥ 140/90 mmHg or on hypertension therapy)  
• HDL cholesterol < 35 mg/dL  
• Triglyceride level > 250 mg/dL  
• LDL cholesterol > 70 and calculated 10-year cardiovascular event risk > 7.5% or on lipid-lowering therapy | |

Benefits:  
Patients can develop T2DM without symptoms, and early detection of diabetes allows for earlier implementation of lifestyle modifications and glucose control, and has a legacy effect that can reduce or prevent complications including retinopathy, neuropathy, nephropathy, peripheral vascular disease, and other microvascular and macrovascular health complications, and reduce the risk of coronary events. Targeted testing for patients with hypertension has shown to be cost effective.

Harms:  
It is unclear for patients with prediabetes that there is a full understanding of which patients will progress to T2DM. Some patients may have increased testing and treatment without benefit, and having the diagnosis of diabetes could potentially have negative psychosocial and economic ramifications for individuals.

Benefits-Harms Assessment:  
Appropriate management of cardiovascular disease and diabetes is supportive of improved mortality and reduction in CVD events with no significant harms to the health of individuals who undergo screening.

Relevant Resources:  
1.3 Screening

**Recommendation**

A clinician should **not** screen for T2DM in asymptomatic patients without additional risk factors.

**Quality of Evidence and Strength of Recommendation**

Quality of Evidence: Low  
Strength of Recommendation: Strong

**Benefits:**

Universal screening incurs substantial costs for initial screening procedures, and many individuals would need to undergo additional testing procedures to confirm or refute the initial screening test, leading to both testing costs and economic costs, such as time away from work or other productive activities. Two randomized trials failed to show a benefit of screening for diabetes on overall mortality. One of these trials found little evidence of benefits from screening on clinical measures of diabetic complications, cardiovascular health, medication use or functional status. In this trial, screening for diabetes appeared to shorten the time to diagnosis of diabetes by only about three years.

**Harms:**

Universal screening would be expected to maximize the number of people diagnosed with diabetes early in their disease process. This would allow for early implementation of therapeutic measures to control hyperglycemia, resulting in a hopefully cost-effective intervention to reduce the incidence of later diabetes-related complications. A randomized trial of screening for diabetes found no evidence of adverse effects of screening on physical or emotional health of screened compared to unscreened individuals.

**Benefits-Harms Assessment:**

The absence of clinical benefit as shown in data from randomized trials and increase in costs would argue against a recommendation for universal screening in unselected populations or populations judged to be at low risk for diabetes.

**Relevant Resources:**

1.4 Diagnostic Testing for T2DM and 1.5 Diagnosis of T2DM

**Recommendation**

A clinician should diagnose a patient with T2DM through the use of an A1c test with a threshold \(\geq 6.5\%\), FPG \(\geq 126\) mg/dL or a two-hour plasma glucose \(\geq 200\) mg/dL on a 75g OGTT. Additionally, if a patient has symptoms of hyperglycemia and casual plasma glucose \(\geq 200\) mg/dL, diabetes may be diagnosed.

**Quality of Evidence and Strength of Recommendation**

Quality of Evidence: Low  
Strength of Recommendation: Strong

**Benefits:**

A1c testing does not require fasting like other methods of testing, which may increase the likelihood that a patient will undergo testing for T2DM and have appropriate diagnosis and treatment. A1c testing also measures chronic glucose exposure over a two- to three-month period and is less influenced by internal factors including stress and/or illness than FPG or OGTT. Both OGTT and FPG are not influenced by abnormal red cell turnover conditions, and both allow for clear guidelines of diagnosis, especially for those who have normal fasting blood sugars.

**Harms:**

A1c testing may miss a portion of the population that would be diagnosed with T2DM using FPG or OGTT criteria, including those that have an abnormal hemoglobins or conditions that affect red blood cell turnover. There may also be racial or ethnic differences in the relationship between glycemia and A1c levels, and these could result in false-negatives or false-positives. FPG and OGTT both require fasting, which may reduce screening rates, and decrease appropriate diagnosis and management due to convenience. The two-hour OGTT is time consuming in both patient fasting and administration.

**Benefits-Harms Assessment:**

The general acceptance of all three testing methods and the specific thresholds are well established. Providing a choice of testing methods is likely to increase the likelihood that appropriate patients are tested for diabetes, minimize cost and inconvenience, and allow clinicians to individualize test selection based on individual patient characteristics.

**Relevant Resources:**

**Supplemental Information**

In the absence of unequivocal hyperglycemia, an abnormal A1c, fasting glucose or oral glucose tolerance test result that meets criteria for diabetes should be confirmed by repeat testing before assigning a diagnosis of T2DM.

- It is preferable that the same test be repeated for confirmation of diabetes. There may be cases in which two different tests are available (e.g., A1c and fasting glucose). If both tests meet diagnostic criteria for diabetes, a diagnosis of diabetes can be made.
2. Diagnosis of Prediabetes

**Prediabetes.** Prediabetes is defined as hyperglycemia that is not sufficient to meet the diagnostic criteria for diabetes, but that is associated with an increased risk of progression to T2DM. Diagnosis of prediabetes is made when an individual meets one or more of the following criteria:

- A1c 5.7-6.4%
- Fasting plasma glucose of 100 mg/dL to 125 mg/dL
- Oral glucose tolerance test two-hour plasma glucose: 140 mg/dL to 199 mg/dL

2.1 Treatment to Prevent or Delay Progression to T2DM

Patients who are identified with prediabetes should be referred for education and life-style interventions to a qualified health professional (which may include clinician, dietitian, nursing staff and pharmacist).

Intensive lifestyle change or programs have been proven effective in delaying or preventing the onset of diabetes by about 50-58%. Effective lifestyle changes include setting achievable goals, obtaining weight loss when needed (between 5-10% of total body weight is recommended), and increasing physical activity to a minimum of 150 minutes per week (Tuomilehto, 2001).

- Patients with IGT, IFG or an A1c should be referred to an effective ongoing support program targeting weight loss of 7% of body weight and increasing physical activity to at least 150 minutes per week of moderate activity such as walking.
- Metformin therapy for prevention of T2DM may be considered in those patients meeting criteria for prediabetes.
- At least annual monitoring for the development of diabetes in those with prediabetes may be utilized.
- Screening for and treatment of modifiable risk factors for CVD are suggested.

**Patients who respond to lifestyle interventions:**

**Patients who are high risk and not responding to lifestyle interventions:**

- Intensify education and counseling on lifestyle interventions. Lifestyle change remains the preferred method to prevent diabetes.

Health care clinicians should follow patients diagnosed with prediabetes on an annual basis to monitor his/her progress and review treatment goals (American Diabetes Association, 2014).
Management Algorithm Annotations

3. Inpatient Diabetes Management

Inpatient care may be appropriate in the following situations (American Diabetes Association, 2004a):

- Elderly patients with infection or illness, weight loss, dehydration, polyuria or polydipsia
- Life-threatening acute metabolic complications of diabetes:
  - Hyperglycemic hyperosmolar state with impaired mental status, elevated plasma osmolality that includes plasma glucose greater than 600 mg/dL
  - Diabetic ketoacidosis with a plasma glucose greater than 250 mg/dL, arterial pH less than 7.30 and serum bicarbonate level less than 15 mEq/L and the presence of moderate ketonuria and/or ketonemia
  - Hypoglycemia with neuroglycopenia that includes blood glucose less than 50 mg
- Uncontrolled insulin-requiring diabetes during pregnancy
- Surgery, infection, steroids – if these conditions cause significant hyperglycemia and rapid initiation of rigorous insulin is needed

Hospitalized patients with diabetes suffer increased morbidity, mortality, length of stay and other related hospital costs compared to non-hyperglycemic inpatients. These negative outcomes are observed more frequently in hospitalized patients with newly discovered hyperglycemia. Hyperglycemia is an independent marker of inpatient mortality in patients with undiagnosed diabetes (Umpierrez, 2002).

Hyperglycemia has been associated with increased infection rates and poorer short-term and long-term outcomes in critically ill patients in the intensive care unit, post-myocardial infarction and post-surgical settings. Earlier studies supported that aggressive glucose management in medical and surgical patients improves outcomes (Van den Berghe, 2001). More recently, intensive management has been linked to increased hypoglycemia and increased mortality in a subset of patients including those with a long history of diabetes and cardiovascular disease (NICE-SUGAR Study Investigators, The, 2009).

The following are suggestions for the inpatient setting (American Diabetes Association, 2014; Clement, 2004):

- Insulin therapy with intravenous insulin in critically ill patients (Van den Berghe, 2001)
- Oral glycemic agents may need to be held or the dose adjusted if the patient is hospitalized
- Use of scheduled insulin, with basal coverage (improves glucose control compared to sliding scale coverage alone)
- For insulin-deficient patients, despite reductions or the absence of caloric intake, basal insulin must be provided to prevent diabetic ketoacidosis
- Target preprandial plasma glucose levels to 90-140 mg/dL (American Diabetes Association, 2014; NICE-SUGAR Study Investigators, The, 2009; American Diabetes Association, 2004a; Clement, 2004; Garber, 2004)
- Target random plasma glucose to less than 180 mg/dL (American Diabetes Association, 2014; Holman, 2009; NICE-SUGAR Study Investigators, The, 2009; American Diabetes Association, 2004a; Clement, 2004; Garber, 2004)
- A protocol should be utilized for patients with hypoglycemia < 70 mg/dL (American Diabetes Association, 2014; Cryer, 2003)
• Establishing a multidisciplinary team that sets and implements institutional guidelines, protocols and standardized order sets for the hospital results in reduced hypoglycemic and hyperglycemic events

Other considerations include (Clement, 2004):

• For patients who are alert and demonstrate accurate insulin self-administration and glucose monitoring, insulin self-management should be allowed as an adjunct to standard nurse-delivered diabetes management.

• Patients with no prior history of diabetes who are found to have hyperglycemia (random fasting blood glucose greater than 125 mg/dL or random glucose of 200 mg/dL or more) during hospitalization should have follow-up testing for diabetes within one month of hospital discharge (Umpierrez, 2002).

Types of Insulin

Based on outpatient studies, consider insulin Glargine or Detemir as the basal insulin (there are limited inpatient studies to date). In studies comparing Glargine to NPH, the risk of nocturnal hypoglycemia was reduced (Wang, 2003; Yki-Järvinen, 2000). Treatment with insulin Detemir resulted in more predictable glycemic control than NPH insulin (Vague, 2003).

Consider using rapid-acting insulin analogs (e.g., lispro, aspart, glulisine instead of regular insulin) unless the patient is to have nothing by mouth or is on continuous feedings. Initial studies comparing rapid-acting insulin with human regular insulin show rapid-acting insulins to be more effective at reducing the peak postprandial glucose concentration (Reynolds, 2004). They may also lower the demand for endogenous insulin, provide superior postprandial glycemic control, and cause fewer hypoglycemic episodes requiring medical intervention (Rave, 2006; Pettitt, 2003; Gerich, 2002).

Insulin lispro, glulisine and aspart have similar pharmacokinetics; they have an earlier onset and peak of action than regular insulin. Peak action usually occurs at one hour with a duration of three to four hours, while regular insulin has a peak action of two to four hours and a duration of six to eight hours. Lispro, glulisine and aspart may then reduce the occurrence of late postprandial hypoglycemia compared to regular insulin (Guerci, 2005; John, 2004).

Insulin Dosing Schedule

Insulin dosing schedules must be individualized based on a variety of factors, including the severity of diabetes, oral intake, severity of illness and other concurrent diabetic medication. It is not feasible to design a single algorithm for determining an insulin regimen in every patient. The following information provides general guidance in determining initial insulin doses.

Healthy, non-diabetic people are estimated to secrete approximately 0.4-1.0 units of insulin/kg body weight per day (Polonsky, 1988a; Davidson, 1986). Approximately 50% of this insulin is secreted as basal insulin and 50% as postprandial boluses following meals (Polonsky, 1988b). Typical daily insulin doses for people with diabetes range from 0.5 to 0.7 units/kg per day. In the United Kingdom Prospective Diabetes Study of people with T2DM, the median daily insulin dose for people in the intensive insulin treatment arm of the study after a diabetes duration of approximately 12 years was 36 units/day (UK Prospective Diabetes Study Group, 1998a).

Fifty percent of subjects were receiving between 23 and 53 units of insulin per day. The average weight of subjects was 75 kg, so the "average" daily insulin requirement was about 0.5 units/kg (UK Prospective Diabetes Study Group, 1998a). Therefore, in initiating subcutaneous insulin in a hospitalized patient who is eating meals, a total daily insulin dose of 0.6 units/kg is probably reasonable (Clement, 2004).
can be made based on clinical judgment for factors such as severity of illness, fragility, renal function, body weight, expected nutritional intake and medication effects (e.g., glucocorticoid medications).

Based on the normal physiology of insulin release and experience with outpatient regimens for managing diabetes with subcutaneous insulin, it has been recommended that inpatient subcutaneous insulin regimens comprise three components (Clement, 2004):

- A basal insulin component
- A prandial insulin component (for patients eating meals)
- A correction, sometimes referred to as "supplemental," insulin component used to treat hyperglycemia before or between meals (Clement, 2004)

In a small, randomized trial comparing a basal/prandial insulin regimen to a traditional sliding scale insulin regimen in hospitalized patients with T2DM, the basal/prandial insulin regimen resulted in improved glycemic control during the hospitalization. Hospital length-of-stay or incidences of hypoglycemia did not differ between the basal/prandial insulin regimen or the sliding scale insulin regimen (Umpierrez, 2007).

**Basal insulin**

Typical approach is to give 40-50% of the estimated total daily insulin dose as the basal insulin component. Common basal regimens include one injection per day of Glargine insulin, usually given at bedtime or twice daily; Detemir insulin given once daily in the evening or given twice daily; twice-a-day injections of NPH insulin, given at breakfast and either at supper or bedtime; or once-a-day NPH insulin given at bedtime (Vague, 2003). Basal insulin would generally be appropriate for any patient being managed with subcutaneous insulin, whether eating meals, nothing by mouth or receiving nutrition as continuous enteral feeding or total parenteral nutrition (TPN) (Clement, 2004).

**Prandial insulin**

For patients eating meals, several approaches have been suggested to initiate a prandial insulin regimen:

- Divide 50% of the estimated daily insulin requirement into three equal insulin doses given before the three meals.
- Estimate the prandial insulin dose before each meal as 10-20% of the estimated daily insulin requirement.
- Count the carbohydrate content of the meal (one carbohydrate unit = 15 gm of meal carbohydrate), and determine the prandial insulin dose as a set number of units of insulin per meal carbohydrate unit.
- Insulin doses based on grams of carbohydrates consumed.

Typical insulin requirements using this last approach are one to two units of insulin per carbohydrate unit (Clement, 2004).

It is recommended that prandial insulin be given as a rapid-acting insulin analog within 0-15 minutes of the meal (Clement, 2004). Prandial insulin replacement has its main effect on peripheral glucose disposal into muscle. Also referred to as "bolus" or "mealtime" insulin, prandial insulin is usually administered before eating. There are occasional situations when this insulin may be injected immediately after eating, such as when it is unclear how much food will be eaten. In such situations, the quantity of carbohydrates taken can be counted and an appropriate amount of rapid-acting analog can be injected (Clement, 2004).

Patients who are not eating meals will not typically require a prandial insulin component, although they may need periodic correction insulin.
Correction (supplemental) insulin

Correction dose insulin is given in addition to the scheduled basal and prandial insulin in order to correct hyperglycemia. For patients eating meals, it is typically given with meals by simply increasing the rapid-acting insulin dose by an additional amount based on the correction schedule. For patients not eating meals (e.g., nothing by mouth, on continuous enteral feeding, total parenteral nutrition), it is reasonable to give periodic short-acting insulin, either as regular insulin or a rapid-acting analog, based on the correction schedule at four- to six-hour intervals (Guerci, 2005; John, 2004). If rapid-acting insulin is used in this situation, an every-four-hour schedule may be optimal. For regular insulin, a four- to six-hour schedule is reasonable (Clement, 2004).

The correction dose insulin schedule must be individualized for the patient. A typical assumption is that one unit of insulin will lower the blood glucose 50 mg/dL (Hirsch, 2002). An empiric "Rule of 1,700" has been proposed as one way of estimating the insulin correction requirement. This rule estimates that the decrease in glucose in response to one unit of insulin = (1,700/patient's total daily insulin dose) (Davidson, 2003). The "Low," "Medium" and "High" correction schedules included on the order set assume that one unit of insulin will lower the blood glucose by approximately 50, 25 and 15 mg/dL, respectively.

There does not appear to be a consensus whether correction insulin should be given at bedtime. Some experts argue against bedtime correction insulin due to a fear of nocturnal hypoglycemia with short- or rapid-acting insulin given at bedtime (Hirsch, 1995). If correction insulin is given at bedtime, the recommendation is that the correction dose should be reduced (Clement, 2004).

Hyperglycemia induced by corticosteroid therapy is often characterized by predominant postprandial hyperglycemia with lesser effects on fasting glucose levels. For patients with corticosteroid-induced hyperglycemia, caution is suggested in prescribing correction dose insulin at bedtime due to the increased risk of nocturnal hypoglycemia (Clement, 2004).

Example:

The following is an example of one possible initial subcutaneous insulin regimen for a hospitalized patient weighing 100 kg with hyperglycemia who is eating meals.

Estimated total daily insulin dose = 100 kg x 0.6 units insulin/kg = 60 units of insulin daily.

Basal: 50% of total daily insulin dose = 30 units given as Glargine or Detemir insulin at bedtime.

Prandial: 50% of total daily insulin dose/3 = 30 units/3 = 10 units of insulin at each meal given as Lispro, Glulisine or Aspart insulin.

Correction schedule: Assuming 1 unit of insulin will drop the blood glucose 50 mg/dL, the "Low" correction schedule on the order set could be used. Using the Rule of 1,700, one would estimate that one unit of insulin = drop in blood glucose of (1,700/60) = 28 mg/dL. In this case, the "Medium" correction schedule might be chosen.

Whatever insulin regimen is initially implemented, it will likely need to be modified over the course of a patient's hospitalization. If a patient is frequently requiring use of the correction schedule, common sense would dictate that either the basal component, prandial component or both need to be modified.

Transition from Intravenous to Subcutaneous Insulin

When transitioning from intravenous to subcutaneous insulin, it is generally recommended that an initial subcutaneous basal insulin dose of long- or intermediate-acting insulin be given prior to discontinuation of the intravenous insulin (Furnary, 2006). Based on the absorption profiles of longer-acting insulins, administering the first subcutaneous insulin dose two hours prior to stopping the insulin infusion would appear to
allow sufficient overlap to avoid excessive rebound hyperglycemia when the insulin infusion is discontinued (Furnary, 2006; Clement, 2004).

Determination of the initial basal insulin dose can be made using the guidelines above (e.g., estimating the basal insulin dose as 40-50% of the estimated total daily insulin dose). An alternative method that has been suggested is to estimate the initial basal dose based on the intravenous insulin requirements over a six- to eight-hour period leading up to the transition time. Ideally, this six- to eight-hour period would be a time when the patient was not eating and was not receiving intravenous glucose. The initial basal insulin dose could be calculated as 80% of the estimated 24-hour insulin requirement to provide a margin of safety (Furnary, 2006).

Example:

A patient managed on an intravenous insulin drip is to be transitioned to subcutaneous insulin. Over a recent six-hour period when the patient was not eating and was not receiving intravenous glucose, the patient received a total of 15 units of insulin via the infusion. The estimated 24-hour basal insulin requirement would be 15 x 4 = 60 units. The initial basal insulin dose could be estimated as 80% x 60 units = 48 units.

Often the clinician may want to use a bedtime long-acting insulin (e.g., Glargine insulin) as the subcutaneous basal insulin, but the transition from intravenous to subcutaneous insulin is planned to occur during the day. In these cases, one option would be to give a one-time dose of NPH insulin by subcutaneous injection to act as a bridge until the regularly scheduled long-acting insulin is given (Clement, 2004). A typical NPH insulin dose might be 40% of the planned long-acting insulin dose.

Example:

Using the example above, the clinician plans to give 48 units of Glargine insulin at bedtime as the basal insulin dose on the transition to subcutaneous insulin. However, the clinician would like to transition the patient to subcutaneous insulin during the day rather than waiting until later in the evening when fewer staff are present. A one-time order for NPH insulin 20 units (40% x 48 units = 19.2 units, round to 20 units) could be written to be given two hours before the insulin infusion is stopped. This intermediate-acting insulin would provide temporary basal insulin coverage until bedtime, when the 48 units of Glargine insulin could be given.

Prandial and correction insulin orders should also be written as appropriate for the patient's situation (eating, on tube feeding, etc.) on transition to subcutaneous insulin. This insulin would then be given in addition to the basal insulin in accordance with the order set.

Medication adherence

Non-adherence with medications can limit the success of therapy and help to explain why a patient is not achieving treatment goals. To screen for non-adherence, clinicians can ask patients open-ended, non-threatening questions at each office visit. The assessment should include probes for factors that can contribute to non-adherence (fear of adverse reactions, misunderstanding of chronic disease treatment, depression, cognitive impairment, complex dosing regimens or financial constraints).

- Assess the patient's knowledge of his/her condition and his/her expectations for treatment
- Assess the patient's medication administration process
- Assess the patient's barriers to adherence

Interventions to enhance medication adherence should be directed at risk factors or causes of non-adherence. Interventions may include simplifying the medication regimen, using reminder systems, involving family or caregivers in care, involving multiple disciplines in team care, providing written and verbal medication
instructions, setting collaborative goals with patients, and providing education about medications (including potential adverse effects) and about diabetes in general (Nichols-English, 2000).

**Depression evaluation**

There is a substantial increase in the prevalence of depression among people with diabetes as compared to the general adult population (Anderson, 2001). Depression impacts the ability of a person with diabetes to achieve blood glucose control, which in turn impacts the rate of development of diabetes complications (de Groot, 2001; Lustman, 2001).

Identification and management of depression are important aspects of diabetes care. Self-administered or professionally administered instruments, such as PHQ-9, are useful adjuncts to the clinical interview in the identification of depression. The ICSI Major Depression in Adults in Primary Care guideline provides more suggestions for the identification and management of depression. Intervention studies have demonstrated that when depression is treated, both quality of life and glycemic control improve. Counseling may be effective, especially among those who are having difficulty adjusting to the diagnosis of diabetes or are having difficulty living with diabetes. Pharmacotherapy for depression is also effective.

**Obstructive sleep apnea**

Sleep apnea is a prevalent condition in obese patients with T2DM and is associated with significant comorbidities including hypertension, cardiovascular disease and insulin resistance. Consider referral of symptomatic patients for sleep evaluation. Clinicians should be cognizant of potential obstructive sleep apnea, especially among obese patients (Foster, 2009a; Foster, 2009b).

**Referral to an Extended Care Team**

**Diabetes educator**

Consultation with a diabetes educator is suggested if the patient is having difficulty adhering to a nutrition, exercise and medication regimen, and the patient is having difficulty adhering to or accurately completing blood glucose monitoring or may need answers to his/her questions.

Primary care clinician should develop a relationship with a diabetes education program to provide other options for management. The American Diabetes Association publishes a list of recognized educational programs in each state. These programs may be staffed with endocrinologists or primary care clinicians plus diabetes educators including dietitians, nurses and other health care clinicians who are Certified Diabetes Educators or have didactic and experiential expertise in diabetes care and education.

**Endocrinologist/nephrologist**

Most T2DM management can be managed by a primary care clinician with periodic consultation as needed by an endocrinologist. Consultation with a specialist is suggested if persistent proteinuria, worsening microalbuminuria and elevation in serum creatinine or blood urea nitrogen, or hypertension unresponsive to treatment is seen.

**Endocrinologist/neurologist**

Consultation with a specialist is suggested if neuropathy progresses and becomes disabling.

**Endocrinologist/cardiologist/hypertension specialist**

Consultation with a specialist is suggested if blood pressure is refractory to treatment, or the patient has marked associated postural hypotension or symptoms of coronary artery disease.

*Return to Algorithm*  *Return to Table of Contents*
Foot care specialist

A consultation with a specialist is suggested if the patient is unable to care properly for his/her own feet, needs prescriptive footwear and/or more serious problems such as foot deformities (e.g., Charcot deformity), infected lesions, and ulcers, deformed nails or thick calluses are present.

Ophthalmology/optometry

Retinopathy is estimated to take at least five years to develop after the onset of hyperglycemia begins. Patients with T2DM who generally have had years of undiagnosed diabetes and who have a significant risk of prevalent diabetic retinopathy at time of diabetes diagnosis should have an initial dilated and comprehensive eye examination soon after diagnosis. Examinations should be performed by an ophthalmologist or optometrist who is knowledgeable and experienced in diagnosing the presence of diabetic retinopathy and is aware of its management. Subsequent examinations are generally repeated annually. Less frequent exams (every two to three years) may be cost effective after one or more normal eye exams, while examinations will be required more frequently if retinopathy is progressing (American Diabetes Association, 2014).

Vascular specialist/surgeon

Consider referral if patient has symptoms of peripheral vascular disease such as loss of pulses and/or claudication.

4. Glycemic Control and A1c Goals

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>A clinician should personalize goals with patients diagnosed with T2DM to achieve glycemic control with a hemoglobin A1c &lt;7% to &lt;8% depending on individual patient factors.</td>
<td>Quality of Evidence: High Strength of Recommendation: Strong</td>
</tr>
</tbody>
</table>

**Benefits:**
Achieving near-normal glycemic control lowers risk of diabetes microvascular complications such as retinopathy, nephropathy and amputations. Achieving A1c of 6.9 to 7.9% may also significantly reduce macrovascular complications based on Steno-2 and UKPDS data.

**Harms:**
Near-normal glycemic control (A1c around 6.4 to 6.5%) achieved through intensive pharmacotherapy appears to have less benefit for major CV events (ACCORD ADVANCE VADT) and in one large trial significantly increased mortality 20% (ACCORD). In some patients, aggressive pharmacotherapy with insulin, sulfonylureas or certain other agents may lead to weight gain and severe hypoglycemia. The long-term cardiovascular safety of agents other than metformin and human insulins has yet to be established.

**Benefits-Harms Assessment:**
Therefore, to optimize the balance between benefits and harms for a given patient, personalization of glycated hemoglobin (A1c) goals in the range of <7% to <8% is recommended.

**Relevant Resources:**

**Supplemental Information**

For patients with T2DM, an A1c goal of less than 8% may be more appropriate than an A1c goal of less than 7%, when including the following factors:

- Known cardiovascular disease or high cardiovascular risk, and may be determined by the Framingham or ACC/AHA Cardiovascular Risk Calculator, or alternatively as having two or more cardiovascular risks (BMI > 30, hypertension, dyslipidemia, smoking and microalbuminuria)
- Inability to recognize and treat hypoglycemia, including a history of severe hypoglycemia requiring assistance
- Inability to comply with standard goals, such as polypharmacy issues
Diagnosis and Management of Type 2 Diabetes Mellitus in Adults
Sixteenth Edition/July 2014

- Limited life expectancy or estimated survival of less than 10 years.
- Cognitive impairment.
- Extensive comorbid conditions such as renal failure, liver failure and end-stage disease complications.

A multifactorial approach to diabetes care that includes emphasis on blood pressure, lipids, glucose, aspirin use and non-use of tobacco will maximize health outcomes far more than a strategy that is limited to just one or two of these clinical domains (American Diabetes Association, 2014; Duckworth, 2009; Gaede, 2008; Holman, 2008a).

**Multifactorial approach**

The benefits of a multifactorial approach to diabetes care are supported by the results of the Steno-2 Study of 160 patients with T2DM and microalbuminuria. Multifactorial interventions achieved a 50% reduction in mortality and significant reduction in microvascular complications five years after ending a 7.8-year multifactorial intervention that achieved A1c of 7.8%, low-density lipoprotein 83 mg/dL, blood pressure 131/73, compared to a conventional group that achieved A1c 9%, low-density lipoprotein 126 mg/dL and blood pressure 146/78 (Gaede, 2008). Results of this study are consistent with the need for reasonable blood glucose control with emphasis on blood pressure and lipid management.

**Microvascular/macrovascular complications**

Follow-up data from the United Kingdom Prospective Diabetes Study of newly diagnosed patients with T2DM confirm major macrovascular and microvascular benefits of achieving A1c in the 7.1 to 7.3% range, versus A1c of about 8% in the comparison groups (Holman, 2008a). The United Kingdom Prospective Diabetes Study main trial included 3,867 newly diagnosed T2DM patients and showed over a 10-year period a 25% decrease in microvascular outcomes with a policy using insulin and sulfonylureas that achieved a median A1c of 7.1%, compared to 7.9%. A subgroup of obese patients (n=1,704) treated with metformin and achieving a median A1c of 7.3% showed greater advantages over conventional treatment: a 32% reduction of diabetes-related end points (P=0.002), a 42% reduction of diabetes-related deaths (P=0.017), and a 36% reduction of all-cause mortality (P=0.011) (UK Prospective Diabetes Study Group, 1998b).

Several reported clinical trials have evaluated the impact of A1c less than 7% on macrovascular and microvascular complications of T2DM. These studies – the Action to Control Cardiovascular Risk in Diabetes (ACCORD), the Action in Diabetes and Vascular Disease: Preferax and Diamcron Modified Release Controlled Evaluation (ADVANCE), and VADT Trials – are the first that have ever achieved and maintained A1c less than 7% in his/her intensive treatment patients.

**Cardiovascular risk**

In the ACCORD Trial, excess mortality in the intensive group (A1c mean 6.4% vs. standard group A1c 7.5%) forced the safety board to discontinue the intensive treatment arm earlier than planned (ACCORD Study Group, The, 2008). There was one excess death for every 90 patients in the intensive group over a 3.5-year period of time. In the ADVANCE trial, intensive group patients achieved A1c 6.5% (vs. 7.5% in standard group) but had no reduction in cardiovascular complications or events. In the VADT trial, intensive group patients achieved A1c of 6.9% but had no significant reduction in cardiovascular events or microvascular complications compared to standard group patients who achieved A1c of 8.4%. However, the VADT Trial was underpowered for its main hypothesis tests (Duckworth, 2009). In the ADVANCE trial, intensive group patients had less progression to proteinuria (one less patient advancing to proteinuria for every 100 people in the intensive group over a five-year period of time), but no fewer eye complications in the intensive group than in the standard group. ACCORD analysis showed lower rates of early stage microvascular complications in the intensively treated group. Some patients, especially those with little comorbidity and long life...
expectancy, may benefit from more intensive glycemic goals as long as hypoglycemia does not become a barrier. However, the risk of lower glycemic targets may outweigh the potential benefits on microvascular complications for many patients (Ismail-Beigi, 2010; ACCORD Study Group, The, 2008).

A meta-analysis analyzed five randomized controlled trials (UKPDS, PROactive, ADVANCE, VADT and ACCORD) for the effect of intensive glucose control on cardiovascular outcomes. Overall, this meta-analysis concluded that more intensive glucose control significantly reduced non-fatal myocardial infarct events and coronary heart disease events (non-fatal myocardial infarct and all-cardiac mortality) with no evidence of either a benefit or adverse effect on all-cause mortality. Heterogeneity among studies was noted with regard to all-cause mortality, suggesting that the impact of glycemic reduction on all-cause mortality may differ among different populations (Ray, 2009). A subset analysis from ACCORD, ADVANCE and VADT suggested that intensive glucose lowering has a modest (9%) but statistically significant reduction in major CVD outcomes, primarily non-fatal MI, with no significant effect on mortality. However, a pre-specified subgroup analysis suggested that major cardiovascular disease outcome reduction occurred in patients without known cardiovascular disease at baseline (Turnbull, 2009).

Glycosylated hemoglobin assays

Glycosylated hemoglobin assays provide an accurate indication of long-term glycemic control. Glycated hemoglobin is formed by the continuous non-enzymatic glycosylation of hemoglobin throughout the lifespan of an erythrocyte. The A1c assay yields an accurate measure of time-averaged blood glucose during the previous six to eight weeks. Clinically, it can assist in determining duration and severity of hyperglycemia and can help guide treatment.

Eating, physical activity or acute metabolic stress does not influence the A1c test. The test can be done at any time of day and does not require fasting.

Self-monitoring blood glucose (SMBG)

Self-monitoring blood glucose (SMBG) allows patients to evaluate his/her individual response to therapy and assess whether glucose targets are being achieved. Results of SMBG can be useful in preventing hypoglycemia and adjusting medications, medical nutrition therapy and physical activity (American Diabetes Association, 1994).

Major clinical trials assessing the impact of glycemic control on diabetes complications have included self-monitoring blood glucose testing (SMBG) as part of multifactorial interventions, suggesting that self-monitoring blood glucose is a component of effective therapy (American Diabetes Association, 2014). Several diabetes management strategies reliant on SMBG testing have demonstrated improved glucose control in patients (Polonsky, 2011; Weinger, 2011).

Table 1 gives ranges of self-monitored glucose readings that would be expected as goals for patients with the corresponding A1c level goals.

* It is not recommended to achieve target fasting glucose values below 70 mg/dL.
** This average uses both fasting and post-prandial blood glucose readings from continuous glucose monitors or from 7-point daily testing.

Table 1 was developed by the diabetes work group based on data currently available from studies of frequently monitored glucose values and will be modified if necessary as further studies become available.

The frequency and timing of SMBG should be dictated by the particular needs and goals of the individual patient. Bedtime glucose goals vary dependent on the patient's treatment program, risks for hypoglycemia and time after last meal. Patients with T2DM on insulin typically need to perform self-monitoring blood glucose more frequently than those not using insulin, particularly if using glucose readings to guide mealtime insulin dosing. It is recommended that patients using multiple insulin injections perform SMBG prior to meals, snack or exercise or when low blood glucose is questioned (American Diabetes Association, 2014). The optimal frequency and timing of SMBG for patients with T2DM on oral or non-insulin injectable therapy are not known but should be sufficient to facilitate reaching glucose goals. SMBG should be performed more frequently when adding or modifying therapy; two-hour post-prandial glucose testing is useful in some patients. The role of SMBG in stable diet-treated patients with T2DM is not known.

Because the accuracy of SMBG is instrumental and user dependent, it is important for health care clinicians to evaluate each patient's monitoring technique and accuracy of equipment. In addition, optimal use of SMBG requires proper interpretation of the data. When appropriate, patients can be taught how to use the data to adjust food intake, exercise or pharmacological therapy to achieve specific glycemic goals.
## 5. Education and Self-Management

### 5.1 Nutrition Therapy

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A qualified health professional (which may include a clinician, dietitian, nursing staff and pharmacist) should provide nutrition therapy to a patient diagnosed with T2DM as part of a global treatment plan. | Quality of Evidence: Moderate  
Strength of Recommendation: Strong |

**Benefits:**
Nutrition therapy specifically activates patients by more intensively assessing eating and physical activity behaviors and nutrient intake, and provides counseling that results in improved health and may reduce complication of T2DM. Diabetes nutrition therapy can result in cost savings and improved outcomes such as reduction in A1c. Nutrition therapy can be personalized based upon the patient’s needs, comorbidities, existing chronic conditions and other key factors.

**Harms:**
Professionals who do not utilize evidence-based standards/protocols can promote expensive short-term strategies that limit food choices – without scientific evidence – that are not ultimately effective in improving long-term health. Patient activation can be difficult and may not be sustainable for the patient long term, and the increased cost for healthy foods may be a burden for some.

**Benefits-Harms Assessment:**
The benefit of having a patient activated and counseled based upon his/her needs and the increase of risk reduction outweighs the difficulty in achieving nutrition modification.

**Relevant Resources:**

<table>
<thead>
<tr>

</thead>
</table>
| A qualified health care professional (which may include a clinician, nursing staff, pharmacist, and registered dietitian) should counsel a patient diagnosed with T2DM to modify his/her diet to reduce sodium intake to < 2,300 mg/day (Strong). Clinicians may counsel patients diagnosed with T2DM and hypertension to further reduce their sodium intake (Weak). | Quality of Evidence: High  
Strength of Recommendation: Strong/Weak |

**Benefits:**
Incrementally lower sodium intakes have shown beneficial effects on blood pressure and mitigation of cardiovascular risk factors with such meal plans as the DASH diet.

**Harms:**
There is difficulty in achieving both low-sodium recommendations and a nutritionally adequate diet, given such concerns as cost, palatability and availability of lower sodium food products.

**Benefits-Harms Assessment:**
The beneficial effects on blood pressure and mitigation of cardiovascular risk factors outweigh the inconvenience and cost of finding a diet with a reduced sodium intake. Sodium intake < 1,500 mg/day has shown to be associated with a small increase in mortality, and counseling a patient to reduce sodium intake to < 2,300 mg/day should be considered only on an individual basis with consideration.

<tbody>
<tr>
<td>Quality of Evidence: Moderate</td>
</tr>
<tr>
<td>Strength of Recommendation: Weak</td>
</tr>
</tbody>
</table>

#### Benefits:

A customized diabetes meal plan that includes the amount of carbohydrate in meals and snacks to improve postprandial glycemia is effective in achieving glycemic control. Carbohydrate intake has a direct effect on postprandial glucose levels and is the macronutrient most of concern in glycemic management. Simplified plate methods that including portion-controlled carbohydrate food sources may be better suited for patients with numeracy and literacy concerns. Carbohydrate intake from vegetables, fruits, whole grains, legumes and dairy products should be advised over intake from other carbohydrate sources, especially those that contain added fats, sugars or sodium.

#### Harms:

Meal plans that do not adjust for total amount of carbohydrates can result in higher than desired target ranges for postprandial blood glucoses and HgbA1c. If the patient is not given a meal plan at the appropriate literacy level, the ability for the patient to effectively monitor carbohydrates may be difficult and produce less than ideal outcomes.

#### Benefits-Harms Assessment:

Monitoring carbohydrate intake, whether by carbohydrate counting or experience-based estimation, remains a key strategy in achieving glycemic control and outweighs the difficulty in achieving nutrition modification.

#### Relevant Resources:

---

### Supplemental Information

#### Nutrition assessment

Clinicians providing nutrition therapy should complete a nutrition assessment, and provide tailored education and counseling based on the individual needs of the person with diabetes. While many standardized meal plans and menus are available in print or Web-based, it is through the collaborative development of individualized nutrition interventions with ongoing support for behavior change that best facilitates achievement of patients' health goals (Evert, 2014). Nutrition education should be delivered by health professionals with appropriate training, knowledge and skills, and of sufficient duration and quality to meet patients' needs effectively (Miller, 2002).

#### Goals and eating patterns

Goals of nutrition therapy for diabetes promote healthful eating patterns designed to lower glucose, blood pressure, and alter lipid profiles to lower cardiovascular risk factors, emphasizing a variety of nutrient-dense foods in appropriate portion sizes to improve overall health (Evert, 2014). Eating patterns or dietary patterns are combinations of different foods or food groups that characterize relationships between nutrition and healthy promotion or disease prevention. Eating patterns include Mediterranean-style, DASH, vegetarian or vegan, low carbohydrate and low fat. Eating plans should take into account individual personal and cultural preferences, health literacy and numeracy, willingness to change behaviors and metabolic goals. Major metabolic goals are to attain individualized glycemic, blood pressure and lipid goals, and achieve and maintain body weight goals to delay and prevent complications of diabetes (Evert, 2014).

#### Macronutrients

A recent systematic review provides evidence that modifying the amount of macronutrients can improve glycemic control, weight and lipids in people with diabetes. Low-carbohydrate, low-glycemic index (GI), Mediterranean and high-protein diets reduced hemoglobin A1c by 0.12-0.5% compared to comparison or control diets. These hemoglobin A1c reductions were significant, with a reduction of 0.5% that was similar to that achieved by using medication and associated with lower risk of microvascular complications (Ajala, 2013). However, while other various meta-analysis and systematic reviews have been conducted, there is no conclusive evidence regarding an ideal macronutrient distribution for all people with diabetes (Evert, 2014). Another recent systematic review found there is no ideal mix of macronutrients that can be applied and that macronutrient proportions should be individualized (Wheeler, 2012).
Meal planning approaches

There are multiple meal planning approaches that can be used as effective nutrition interventions. Examples include carbohydrate counting, simplified healthful food choices (i.e., the Plate Method), and individualized meal plans based on percentages of macronutrients, exchange lists or glycemic index. For individuals using fixed daily insulin doses, consistent carbohydrate intake with respect to time and amount can reduce risk of hypoglycemia and improve glycemic control (Evert, 2014).

Carbohydrate intake

There is insufficient evidence to recommend a specific amount of carbohydrate intake for all people with diabetes. Despite the conflicting evidence evaluating the effect of differing percentages of carbohydrates, monitoring carbohydrates remains a useful strategy. The quantity and the type of carbohydrate in a food influence blood glucose level, and the total amount of carbohydrate is the primary predictor of glycemic response. Therefore, the effect of the amount of carbohydrates and available insulin on postprandial blood glucose should be considered in developing a meal plan. Monitoring carbohydrate intake, either by carbohydrate counting or experience-based estimation, remains a key strategy in achieving glycemic control (Evert, 2014).

Sucrose

It has been demonstrated that the substitution of sucrose for starch for up to 35% of calories may not affect glycemia or lipid levels. Since foods high in sucrose are high in calories, substitution should be made to ensure nutrient density of overall eating pattern. There is evidence from studies of individuals without diabetes that because of rapidly absorbable carbohydrates (such as sucrose or high-fructose corn syrup) large quantities of sugar-sweetened beverages (SSBs) should be avoided to lower risk of weight gain and worsening of cardiometabolic risk factors (Evert, 2014).

Fiber

People with diabetes should consume at least the amount of fiber and whole grain recommended for the general population. Encourage consuming a wide variety of fiber-containing foods such as legumes, fiber-rich cereals, fruits, vegetables and whole grain products to achieve fiber intake goals of 14 g/1,000 calories or about 25 g/day for adult women and 38 g/day for adult men, and meet recommendations to consume at least half of all grains as whole grains (Evert, 2014).

Glycemic index

A recent systematic review on low-glycemic index diets concluded a low-GI diet can decrease HgbA1c by 0.5%, which was statistically significant (Thomas, 2009). Substituting low-glycemic load foods for higher-glycemic load foods may modestly improve glycemia. The ADA nutrition guideline states the evidence evaluating the effect of glycemic index or glycemic load is complex and often difficult to discern the independent effect of fiber compared to that of glycemic index on glycemic control or other outcomes (Evert, 2014). With a lack of a standard definition of a low-glycemic food and different responses in individuals, it is difficult to teach this method to patients. Consideration of glycemic effects of a mixed meal makes it even more difficult to include this in meal planning, especially for those patients with numeracy concerns. Patients who already are competent carbohydrate gram counters perhaps best utilize use of glycemic index or load food lists.

Non-Nutritive sweeteners

There is little evidence that use of non-nutritive sweeteners (NNSs) leads to reduction in body weight. If NNSs are used to replace caloric sweeteners without caloric compensation, then NSSs may be useful in reducing caloric and carbohydrate intake (Wiebe, 2011).
Protein

For people with diabetes and no evidence of diabetic kidney disease, evidence is inconclusive to recommend an ideal amount of protein intake for optimizing glycemic control or improving one or more CVD risk measure. While some randomized control trials have compared the effect of higher protein diets to usual intake on diabetes outcomes, they have been small and of short duration. For people with diabetic kidney disease, reducing the amount of protein below usual intake is not recommended because it does not alter glycemic measures, cardiovascular risk measures or the course of glomular filtration rate (GFR) decline. Protein appears to increase insulin response without increasing plasma concentrations, therefore carbohydrate sources high in protein should not be used to treat hypoglycemia (Evert, 2014).

Fat intake

Evidence is inconclusive for an ideal amount of total fat intake, so fat goals should be individualized to be consistent with goals to either maintain or lose weight. The Institute of Medicine recommendations define acceptable macronutrient distribution for total fat as 20-35% of calories. The type of fatty acids consumed is more important than the total dietary fat in supporting metabolic goals and influencing risk of cardiovascular disease (Evert, 2014). The 2013 AHA/ACC Lifestyle Management to Reduce Cardiovascular Risk guideline recommends reduce percent of calories from saturated fat to 5-6% (Stone, 2014).

Monounsaturated fatty acids (MUFA)

The Mediterranean-style mono-unsaturated fatty acid-rich eating pattern is associated with improved glycemic control and reduction in cardiovascular risk factors, and can be utilized as an effective alternative to lower-fat, higher-carbohydrate eating patterns. Studies demonstrated improvements when MUFA (monounsaturated fatty acids) was substituted for carbohydrates and/or saturated fats, but some of the studies included a caloric restriction, which may have contributed to positive outcomes (Evert, 2014). A recent randomized trial, the PREDIMED trial, enrolled subjects with either T2DM or at least three CVD risk factors. The authors concluded an energy-unrestricted Mediterranean diet, supplemented by either extra-virgin olive oil or nuts, resulted in a substantial reduction in the risk of major cardiovascular events among high-risk persons and supported the benefits of the Mediterranean diet for the primary prevention of cardiovascular disease (Estruch, 2013).

Omega-3

An increase in foods containing Omega-3 fatty acids (EPA and DHA from fatty fish) and ALA is recommended because of beneficial effects on lipoproteins, and prevention of heart disease and associations with positive outcomes in observational studies. Evidence does not support recommending omega-3 supplements for the prevention or treatment of cardiovascular events (Evert, 2014).

Sodium

A systematic review of randomized control trials showed that decreasing sodium intake reduces blood pressure in people with diabetes (Suckling, 2010). The Institute of Medicine report suggested there is no evidence on health outcomes to treat certain population subgroups – including people with diabetes – differently than the U.S. population in regards to the amount of salt reduction (Institute of Medicine, 2013).

Alcohol

If one chooses to drink alcohol and has not been cautioned against it, limit intake to one drink per day for women and two drinks per day for men, according to USDA guidelines. A drink is defined as 12 oz. of regular beer, 5 oz. of wine, or 1.5 oz. of 80-proof distilled spirits. To reduce the risk of hypoglycemia, alcohol should be consumed with food, especially if taking insulin or insulin secretagogues.
5.2 Physical Activity

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A clinician should advise patients diagnosed with T2DM to complete at least 150 minutes a week of aerobic physical activity and resistance training at least twice per week. | Quality of Evidence: High  
Strength of Recommendation: Strong |

**Benefits:**
Exercise is a low-cost, non-pharmacological intervention that has been shown to have a beneficial effect on decreasing metabolic risk factors for the development of complications and cardiovascular disease. Lowering glucose may reduce medication needs via muscle mass development, HGBA1c levels, improve insulin sensitivity, bone density and balance; and it is well tolerated, feasible and safe.

**Harms:**
Behavior modification may be difficult and challenging to maintain. Concern is that acute rises in blood pressure associated with higher intensity resistance exercise might be harmful, possibly provoking stroke, myocardial ischemia or retinal hemorrhage. Also muscle soreness, fatigue and injury potential are additional harms that may be associated with physical activity.

**Benefits-Harms Assessment:**
The benefit that exercise has shown to provide in lowering the effects of T2DM and its cost saving outweigh the difficulty in achieving behavior modification and the low risk of cardiovascular events due to acute rises in blood pressure.

**Relevant Resources:**
Gibbs, 2014; Look AHEAD Research Group, The, 2013; Church, 2010; Li, 2010; Diabetes Prevention Program Research Group, 2009; Orozco, 2008; Thomas, 2006; Cauza, 2005; Sigal, 2004; Castaneda, 2002; Dunstan, 2002; Boulé, 2001

**Supplemental Information**

The positive benefits of physical activity include improved glycemic control, blood pressure values, lipid profile, depression management and cardiac status, as well as increased insulin sensitivity and effective weight management.

Hypoglycemia is a risk in individuals who participate in physical activity and are taking insulin and/or insulin secretagogues. Depending on the level of physical activity, the medication dosage or the amount of carbohydrate ingested, hypoglycemia can occur. For patients on these drug classes and pre-exercise glucose monitor results are less than 100 mg/dL., additional carbohydrate should be ingested for prevention of hypoglycemia.

**Strategies for initiation of increased physical activity**

- Start by incorporating 10 minutes of increased activity into each day
  - Use stairs instead of elevator
  - Park car away from building entrance and walk
  - Walk to do errands
- Overcome barriers
  - Self-monitor activity performed using pedometer, time record and/or journal
  - Be consistent
  - Have alternative activities for inclement weather
  - Find enjoyable activities
  - Be active at the time of day that is best for the individual
  - Doing a physical activity with a partner and/or being accountable to someone regarding your progress greatly improves the ability to be successful
- Reinforce the ongoing need and benefits of physical activity at each visit
Medical evaluation to assess safety of exercise program

Clinicians should use clinical judgment and assess for conditions that might contraindicate certain types of exercises or be predisposed to injury (e.g., uncontrolled hypertension, severe autonomic neuropathy, severe peripheral autonomic neuropathy or history of foot lesions). High-risk patients should be encouraged to start with short periods of low-intensity exercise, and increase intensity and duration slowly (American Diabetes Association, 2014).

- Assess physical condition and limitations of the patient
- Cardiac stress testing should be considered for the previously sedentary individual at moderate to high risk for cardiovascular disease or other patients who are clinically indicated who want to undertake vigorous aerobic exercise that exceeds the demands of everyday living (American Diabetes Association, 2014). Cardiac stress testing is not routinely necessary in asymptomatic patients before beginning a moderate-intensity exercise program such as walking.
- Assess glucose control
- Assess knowledge of physical activity in relation to glucose control
- When making a referral, make other health care clinicians aware of limitations for exercise

5.3 Weight Management

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>A qualified health professional (which may include a clinician, dietitian, nursing staff and pharmacist) should counsel an overweight patient diagnosed with T2DM about the need to reduce energy intake while maintaining a healthful eating pattern to promote weight loss.</td>
<td>Quality of Evidence: Moderate Strength of Recommendation: Strong</td>
</tr>
</tbody>
</table>

Benefits:
Various energy-restricted eating patterns have been utilized to reduce excess body weight with no specific optimal macronutrient intake to support weight reduction established. A variety of eating patterns has resulted in reduction of energy with weight loss and subsequent improvement in diabetes control and other cardiovascular risk factors.

Harms:
Maintaining a nutritional therapy change maybe difficult for a patient long term and may not be sustained. Unqualified health advisors may recommend overly restrictive diet regimens that result in nutritional deficiencies and/or rapid extreme weight loss, which may contribute to medical conditions such as gallstones.

Benefits-Harms Assessment:
The benefits of a healthier lifestyle outweigh the harms associated with sustainability and the potential for nutritional deficiencies or rapid extreme weight loss. Weight loss and a healthier lifestyle are difficult to sustain, but even small amounts of weight loss and reduction in energy intake can improve outcomes.

Relevant Resources:

Supplemental Information

Because many individuals with T2DM are insulin resistant and overweight or obese, nutrition therapy often begins with strategies that reduce energy intake and increase energy expenditure through physical activity. The optimal macronutrient distribution of weight loss diets has not been established. Studies designed to reduce excess body weight have used a variety of energy-restricted eating patterns with various macronutrient intake, and some included physical activity and ongoing follow-up support. Clinicians should collaborate with overweight or obese individuals with diabetes to develop healthful eating plans that reduce energy to promote weight loss. An eating plan should include appropriate food choices, and portion size needs to reflect energy requirements to ensure appropriate energy balance (Evert, 2014).

Maintenance of weight loss requires an intensive program with long-term support (Evert, 2014). One study concluded the failure of initial weight loss of 6% after 12 weeks of intensive weekly contact with improvement in glycemic control to be sustained at an 18-month follow-up was likely due to a lack of continued
contact with a health professional (Ash, 2003). A study comparing a high-monounsaturated fat diet to a high-carbohydrate diet concluded only the high-monounsaturated fat diet group was able to maintain weight loss at 18 months compared to the high-carbohydrate diet group (60% carbohydrate). The authors note the intense, year long behavioral intervention delivered by registered dietitians influenced the dietary compliance and positive outcomes achieved in the study (Diabetes Prevention Program Research Group, 2009).

See the ICSI Prevention and Management of Obesity for Adults guideline for recommended lifestyle strategies.

5.4 Bariatric Surgery

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A clinician may recommend a patient diagnosed with T2DM and a BMI > 35 kg/m² consider bariatric surgery if diabetes or comorbidities are difficult to control with lifestyle and pharmacologic therapy. | Quality of Evidence: Moderate  
Strength of Recommendation: Weak |

Benefits:  
Large amounts of weight loss – which can be achieved with bariatric surgery, at least in the short term – in resolution of diabetes or improved diabetes control and elimination or reduction in diabetes medications compared to intensive medical management.

Harms:  
Bariatric surgery carries a risk of perioperative mortality and perioperative, and long-term complications from surgery. Whether bariatric surgery results in long-term reduced mortality or risk of cardiovascular events compared to intensive medical management is unknown.

Benefits-Harms Assessment:  
The potential for resolution or substantial improvement in diabetes with bariatric surgery could outweigh the potential harms from surgery for appropriate patients who wish to consider this option.

Relevant Resources:  
Ikramuddin, 2013; Cohen, 2012; Dorman, 2012; Mingrone, 2012; Schauer, 2012; Maciejewski, 2011; Hoerger, 2010; Makary, 2010; Buchwald, 2009

See the ICSI Prevention and Management of Obesity for Adults guideline for discussion of bariatric surgery.

5.5 General Diabetes Self-Management and Education

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| Diabetes self-management or education by a qualified health care professional (which may include a clinician, dietitian, nursing staff and pharmacist) should be offered to patients diagnosed with T2DM. | Quality of Evidence: High  
Strength of Recommendation: Strong |

Benefits:  
Diabetes self-management education and support improves patient understanding of the disease, empowers patients to manage their care, and reduces distress. It is cost effective and has been shown to improve knowledge, self-efficacy and self-care behavior skills, and modestly improves glycemic control.

Harms:  
Patients may find it difficult to continue education due to the ongoing time commitment and expense.

Benefits-harms Assessment:  
Benefit of providing education and support strongly outweighs any potential harms.

Relevant Resources:  

Diabetes self-management education includes the ongoing processes of facilitating the knowledge, skill and ability necessary for diabetes self-care. It incorporates the needs, goals and life experiences of the person with diabetes. Education helps people with diabetes initiate effective self-management and cope with diabetes when they are first diagnosed. Ongoing diabetes education helps people with diabetes maintain effective self-management throughout a lifetime of diabetes (American Diabetes Association, 2014).

In the U.S., one option for self-management education is the Outpatient Diabetes Self-management and Training Program. This is a service that educates patients on self-management of diabetes and includes
education about self-monitoring of blood glucose, diet, exercise and sometimes medication (oral agents and/or insulin). The treatment plan is developed specifically for the patient, which helps engage and motivate patients to use the knowledge and skills in effective self-management. It follows the national standards for diabetes self-management education programs and American Diabetes Association (ADA) review criteria or the American Association of Diabetes Educators (AADE). Other countries have developed national standards that include many of the same components.

The evidence of the benefits of diabetes self-management education is substantial. Diabetes education is associated with improved diabetes knowledge and improved self-care behavior (Norris, 2005) and improved clinical outcomes such as lower HgbA1c, lower self-reported weight, improved quality of life, healthy coping and lower costs (American Diabetes Association, 2014). A recent meta-analysis suggested that educational and behavioral interventions in T2DM produced a moderate decline in HgbA1c of .43%, which was statistically significant. Larger sample size studies and those with better study quality scores had larger HgbA1c declines (Gary, 2003).

Better outcomes are reported when interventions are longer and include follow-up support; are culturally and age appropriate, and tailored to individual needs, address psychosocial issues and incorporate behavioral strategies. Those interventions that promote behavior change in turn improve clinical outcomes (Steinsbekk, 2012; Radhakrishnan, 2011).

Interventions that have psychosocial content (e.g., discuss quality of life with participants, and include empowerment or motivational interviewing) had a positive rate difference of 80% compared to diet outcomes. The relationship between diet and psychosocial issues is particularly relevant for women from high-risk ethnic groups living with T2DM. Interventions that focus on psychosocial support and self-management have proved successful in some studies among Hispanic and African American populations because they address emotions and beliefs about T2DM, deal with the question of how adjusting one's lifestyle may conflict with cultural norms, and demonstrate that incorporating psychosocial coping strategies may be effective in improving dietary behaviors.

The recent literature provides support for a variety of healthy coping interventions in diverse populations, including diabetes self-management education, support groups, problem-solving approaches, and coping skills interventions for improving a range of outcomes. Coping with an emphasis on problem-solving may benefit psychosocial outcomes in addition to self-care behavior and glycemic control, although more studies evaluating a common set of healthy coping outcomes are needed. There has been substantial interest in cognitive behavioral therapy (CBT), including several studies suggesting effectiveness of CBT-based interventions on depressive symptoms and diabetes-related stress, when delivered via novel formats, such as the Internet and/or telephone. However, evidence from recent trials is mixed (Thorpe, 2013).

A Cochrane review (Deakin, 2009) concluded group-based training for self-management strategies in people with T2DM is effective by improving fasting blood glucose levels, glycated hemoglobin and diabetes knowledge, and reducing systolic blood pressure levels, body weight and the requirement for diabetes medication. An anticipated benefit of diabetes education for patients is improved glycemic control as a consequence of better patient motivation, adherence to treatment and understanding of the disease. A number of recent systematic reviews and a meta-analysis highlight the effectiveness of nurses and dietitians in multiple studies in delivering effective diabetes education (Guicciardi, 2014; Steinsbekk, 2012; Tshiananga, 2012).

While the Diabetes Education and Self-management for Ongoing and Newly Diagnosed (DESMOND) randomized control trial demonstrated the HgbA1c level was not improved in the trial, this may have been because the major improvements in HgbA1c level achieved in the period after diagnosis of diabetes, as seen in both study arms, may have masked any effect of the intervention (Gillett, 2010). A Cochrane review (Duke, 2009) found that individual diabetes education and self-management, compared to usual care, did not significantly improve glycemic control, although there was benefit for those with an A1c greater than 8.0%. Differences in patient characteristics and in education and self-management content and implementation
may have contributed to the variability in outcomes. The review notes the impact may have been diluted by including a high number of participants who had a near normal HgbA1c at baseline. In a subgroup analysis focused on studies where participants had an average baseline HgbA1c of greater than 8%, there was a significant impact of individual education on glycemic control. The authors concluded the systematic review highlighted the benefits of individual education in lowering HgbA1c in a subgroup of patients with poorer control and a mean baseline HgbA1c greater than 8% (Duke, 2009).

The integrated chronic care model (CCM) is increasingly recommended as the preferred model of diabetes care in many countries. While focusing on organization of treatment so that care services are better integrated and more efficiently utilized, an integral component of CCM is support of patient management of patients' own care via diabetes self-management education (Siminero, 2006b).

Although a recent U.S. study based on commercial and Medicare claims databases revealed that patients using diabetes education have lower average medical costs than patients who do not (Duncan, 2011), due to a lack of large-scale population-based trials, the evidence documenting the clinical and economic impact of the CCM approach remains uncertain (Tshiananga, 2012).

A systematic review concluded computer-based diabetes self-management interventions currently have limited effectiveness (Pal, 2013). They appear to have small benefits on glycemic control. The effect size on HgbA1c was larger in the mobile phone subgroup. Current interventions do not show adequate evidence for improving depression, health-related quality of life or weight, but they do appear to be safe (Pal, 2013). Effective nutrition therapy interventions may be part of a comprehensive group education session or an individualized session. Interventions should also include recommendations for physical activity and utilize behavior change counseling to help sustained improved lifestyle modifications (Evert, 2014).

5.6 Foot Care Education

Foot Care Education

Education should be tailored to patient's current knowledge, individual needs and risk factors. Patients should be aware of their risk factors and appropriate measures to avoid complications (American Diabetes Association, 2004d; Mayfield, 1998). See "Comprehensive foot exam with risk assessment" in the "Ongoing Management" section.

Education should include:

- Self-inspect feet daily for cuts, bruises, bleeding, redness and nail problems.
- Wash feet daily and dry thoroughly, including between the toes.
- Do not soak feet unless specified by a health care clinician.
- Be careful of hot water.
- Use of lotions, creams or moisturizer is acceptable, but do not use between the toes.
- Do not walk barefoot.
- Check shoes each day for objects that may have fallen inside, excessive wear or areas that may cause irritation.
- Avoid injuries from cutting toenails; avoid self-cutting calluses or corns.
- When to seek care.
5.7 Tobacco Cessation

Tobacco smoking increases risk of macrovascular complications 4-400% in adults with T2DM and also increases risk of microvascular complications. Over time, tobacco and nicotine products have expanded (including e-cigarettes, water pipes and dissolvable products) and care teams should be advised about these developments in order to screen and counsel appropriately. Tobacco cessation is very likely to be the single most beneficial intervention that is available, and it should be emphasized by clinicians as described below.

- Identify and document tobacco use status.
- Treat every tobacco user. If the patient is unwilling, the clinician should implement motivational treatments.
- Individual, group and telephone counseling are effective, and their effectiveness increases with treatment intensity.
- Practical counseling (problem-solving/skills training and social support delivered as part of the treatment) is an especially effective counseling strategy and should be implemented by clinicians.
- Numerous effective pharmacotherapies for smoking cessation now exist. Except in the presence of contraindications, these may be used with all patients attempting to quit smoking. Please see the ICSI Healthy Lifestyles guideline for additional information.
- The combination of counseling and medication is more effective than either alone. Therefore, clinicians should encourage all individuals making a quit attempt to use both.
- Telephone quitline counseling is effective. Therefore, clinicians and health care delivery systems should ensure patient access to quitlines and promote their use. HHS National Quitline (1-800-QUITNOW) or 1-800-784-8669 connects you to counseling and information about quitting smoking in your state.
- Tobacco dependence treatments are both clinically effective and cost effective. Effective interventions require coordinated interventions. Just as the clinician must intervene with the patient, so must the health care administrator, insurer and purchaser foster and support tobacco intervention as an integral element of health care delivery.
6. Metformin

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A clinician should initiate metformin as first-line pharmacotherapy for patients with T2DM, unless medically contraindicated. | Quality of Evidence: High  
Strength of Recommendation: Strong |

**Benefits:**
Metformin may reduce A1c by 1-1.5%, rarely causes hypoglycemia when used as monotherapy and does not cause weight gain. It is a low-cost, oral medication with a long track record of accumulated patient experience and safety, and it has a beneficial lipid effect. Metformin can also be used in combination with all other glucose-lowering agents. Improved microvascular and macrovascular outcomes have been demonstrated in large clinical trials. In UKPDS, obese patients treated with metformin had reduced complications and overall mortality.

**Harms:**
The most common side effects are diarrhea, gas and nausea. These side effects can be attenuated by initiating metformin at a low dose and increasing gradually over several weeks or months up to the maximum effective dose. The risk of lactic acidosis, a rare but potentially life-threatening condition, may be increased due to metformin but data are controversial. Conditions that predispose patients to hypoxemia, such as symptomatic CHF or COPD can increase the risk of lactic acidosis. The kidneys clear metformin, and the product label contraindications relate to specific creatinine thresholds. However, other data indicate that metformin seems safe and can be initiated in labeled doses if the GFR is above 45 ml/min, with close monitoring of renal function and continued treatment unless the GFR falls to < 30 ml/min. Metformin should be stopped before surgery or contrast studies with radiographic dye injection for at least 48 hours and until adequate post-event renal function is documented. Long-term metformin use has been associated with vitamin B12 deficiency.

**Benefits-Harms Assessment:**
The benefits of metformin outweigh the harms for most patients. Monitoring of renal function and conditions that may predispose to lactic acidosis reduce the potential risk. Metformin alone may not be sufficient to achieve recommended blood glucose goals in patients presenting with severe hypoglycemia.

**Relevant Resources:**

Cardiovascular Risk Management Algorithm Annotations

7. Cardiovascular Risk Factors

7.1 Antihypertensive Therapy

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A clinician should initiate antihypertensive treatment for patients with T2DM with a blood pressure ≥ 140/90 mmHg and treat to a goal of < 140/90. | Quality of Evidence: High  
Strength of Recommendation: Strong |

**Benefits:**
Uncontrolled hypertension is a major risk factor for ASCVD events. Multiple large studies (UKPDS, HOT, ADVANCE) have shown improved cardiovascular outcomes with treatment of blood pressure to this range in patients with diabetes.

**Harms:**
In many patients with diabetes, two or three or more medications are required to achieve this level of blood pressure control. Medications may be costly, and there are risks of adverse reactions, medication interactions and overtreatment causing hypotension.

**Benefits-Harms Assessment:**
Considering the high level of ASCVD risk and the significant benefits for primary and secondary prevention of cardiovascular events in treating hypertension, along with the low cost generic status of the vast majority of antihypertensive medications, it is believed that the benefits of treating hypertension to this goal outweigh the risks. Careful attention should be given to monitoring for side effects, medication interactions and avoiding overtreatment.

**Relevant Resources:**

Supplemental Information

Uncontrolled hypertension is a major cardiovascular risk factor that also accelerates the progression of diabetic nephropathy (Morrish, 1991). When hypertension is identified, it should be aggressively treated to achieve a target blood pressure of less than 140/90 mmHg. In many patients with diabetes, two or three or more antihypertensive agents may be needed to achieve this goal. The use of generic combination tablets (such as ACE plus calcium-channel blocker or beta-blocker plus diuretic) can reduce the complexity of the regimen and out-of-pocket costs.
The UKPDS, HOT, ADVANCE and ACCORD trials are all large randomized clinical trials that allow comparison of more stringent to less stringent blood pressure levels on major cardiovascular outcomes (ACCORD Study Group, The, 2010b; Zoungas, 2009; Hansson, 1998; UK Prospective Diabetes Study Group [UKPDS], 1998b). The UKPDS, HOT and ADVANCE trials all found reduced cardiovascular outcomes with lower achieved blood pressure levels. However, none of these trials achieved average systolic blood pressure levels below 130 mmHg (Table 2). The ACCORD trial found no difference in major cardiovascular outcomes between a more intensive blood pressure intervention targeting systolic blood pressure < 120 mmHg compared to a more standard intervention targeting systolic blood pressure between 130 and 139 mmHg (Table 2). The more intensive blood pressure regimen was associated with a small reduction in the rate of stroke, greater medication use and more serious adverse events (ACCORD Study Group, The, 2010b).

The above studies support a systolic blood pressure goal < 140 mmHg for people with T2DM. We would estimate that targeting a systolic blood pressure < 140 mmHg would result in an achieved blood pressure around 135 mmHg for most people.

Only the HOT trial specifically targeted diastolic blood pressure. In the HOT trial, targeting a lower diastolic blood pressure was associated with fewer cardiovascular events in subjects with T2DM. The average achieved diastolic blood pressure values in the three HOT intervention arms ranged from 81-85 mmHg (Table 2). Based on results from the ADVANCE and ACCORD trials, it appears likely that achieved systolic blood pressure values in the mid-130 range will be associated with diastolic blood pressure values well below 80 mmHg.

The general recommendation from The 2014 Evidence-Based Guideline for the Management of High Blood Pressure in Adults: Report From the Panel Members Appointed to the Eighth Joint National Committee (JNC 8) to treat to a goal of a blood pressure < 140/90 mmHg does not preclude setting individual patient goals lower than that based on patient characteristics, comorbidities, risks or the preference of an informed patient (James, 2014).

While ACE inhibitors and ARBs are preferred first-line therapy, two or more agents (to include thiazide diuretics) may be required. For patients with T2DM, thiazide diuretics in the treatment of hypertension may reduce cardiovascular events, particularly heart failure (James, 2014; Wing, 2003; ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group, 2002; Heart Outcomes Prevention Evaluation Study Investigators, The, 2000; Alkharouf, 1993; Lewis, 1993).
7.2 Statin Therapy (High Risk)

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| (A) A clinician should recommend high-intensity statin therapy for patients diagnosed with T2DM, between the ages of 40-75 with established ASCVD (strong), and (B) may recommend high-intensity statin therapy for others at a 10-year ASCVD risk ≥ 7.5% (weak). | Quality of Evidence: High
Strength of Recommendation: Strong/Weak |

Benefits:
A high-intensity statin reduces the relative risk of ASCVD events more than moderate-intensity statin in patients with and without diabetes, and in primary and secondary prevention in those with diabetes.

Harms:
Serious adverse events such as myopathy and rhabdomyolysis are rare, but patient characteristics that may influence statin safety and be cause for not recommending high-intensity statin therapy include multiple concomitant comorbidities, impaired renal or hepatic function, a history of previous statin intolerance or muscle disorders, concomitant use of drugs known to affect statin metabolism, a history of hemorrhagic stroke and age > 75.

Benefits-Harms Assessment:
The benefits of high-intensity statin therapy for patients with diabetes and high ASCVD risk usually outweigh potential harm, but side effects and individual patient characteristics that predispose patients to statin toxicity can influence the risk/harm balance. Patient preference should be included in decision-making.

7.3 Statin Therapy (Moderate Risk)

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
</table>
| A clinician should recommend moderate- or high-intensity statin therapy for all patients diagnosed with T2DM between the ages of 40-75 with a LDL ≥ 70 mg/dL. | Quality of Evidence: High
Strength of Recommendation: Strong |

Benefits:
The use of at least moderate-intensity statin therapy in persons of this age and an elevated LDL level with a diagnosis of diabetes has been shown to be effective. The only trial of high-intensity therapy in primary prevention was performed in a population without diabetes. High-intensity statin therapy reduces the relative risk of ASCVD events more than moderate-intensity statin therapy in patients with ASCVD. Because individuals with diabetes are at substantially increased lifetime risk for ASCVD events and death, similar to those who have had a previous ASCVD event, persons with diabetes with high estimated 10-year ASCVD risk are likely to benefit similarly from high-intensity therapy.

Harms:
Statin therapy appears to cause only a slight increased risk of side effects compared to placebo, and no increased risk of discontinuation of therapy compared to placebo. In clinical practice, the most common side effect observed is muscle symptoms. Some patients who have muscle symptoms can tolerate lower statin doses, changes in statin drugs or alternate-day dosing. Known statin associated serious adverse effects include rare cases of myopathy, hemorrhagic stroke and drug-drug interactions. There are insufficient data to support benefits in individuals with NYHA class II-IV heart failure and individuals undergoing maintenance hemodialysis. Preferences of patients who understand the risks and benefits of statin use should be accounted for, as the potential benefit (especially for primary prevention) may not outweigh the inconvenience and cost of a long-term daily medication with possible side effects for some people.

Benefits-Harms Assessment:
Given the high prevalence of macrovascular disease in those with diabetes and the cardiovascular benefit of statins clearly exceeds the risk of adverse events and modest cost for most patients with T2DM ages 40-75. Intensifying statin therapy should be discussed with the patient in a shared decision-making conversation including the risks and benefits. Patients with characteristics that might be predispose them to statin side effects may be candidates for lower intensity statin dosing.

Relevant Resources:
Taylor, 2013; Macchia, 2012; AIM-HIGH Investigators, 2011; ACCORD Study Group, The, 2010a; Cholesterol Treatment Trialists’ (CTT) Collaboration, 2010; Cholesterol Treatment Trialists’ (CTT) Collaborators, 2008; Cannon, 2004; Heart Protection Study Collaborative Group, 2002

Supplemental Information
Seventy to seventy-five percent of adult patients with diabetes die of macrovascular disease, specifically coronary, carotid and/or peripheral vascular disease. Diabetes is considered a myocardial infarction risk equivalent to ASCVD risk. Dyslipidemia is a known risk factor for macrovascular disease. Patients with diabetes develop more atherosclerosis than patients without diabetes with the same quantitative lipoprotein profiles. In most patients with diabetes, use of a statin can reduce major vascular events. Beneficial effects of statins on cardiovascular risk reduction may go beyond their quantitative effects on lipid levels.

www.icsi.org
For those with a diagnosis of diabetes who are younger than 40 or older than 75, statin therapy decisions should be individualized based on considerations of ASCVD risk reduction benefits, potential adverse effects and drug interactions, and patient preferences.

For additional information on statin therapy, refer to the ICSI Lipid Management in Adults guideline.

The current evidence does not support the use of combination therapy with statins and other lipid drugs for most patients with T2DM. The National Institutes of Health-sponsored ACCORD lipid study showed no significant reduction in myocardial infarct, stroke or cardiovascular death with a fibrate-statin combination compared to statin monotherapy. However, a subgroup analysis of the primary outcome suggested that there was a gender effect with a possible benefit for men and possible harm for women, as well as a possible benefit for men and women with both low HDL (< 34 mg/dL) and elevated triglycerides (> 204 mg/dL).

AIM-HIGH was a study designed to evaluate the cardiovascular outcomes with niacin and statin combination therapy compared to statin monotherapy in patients with coronary heart disease, including a subgroup with diabetes. The study was stopped early in 2011 because of lack of benefit compared to statin therapy alone, including the diabetes subgroup (AIM-HIGH Investigators, 2011).

### 7.4 Aspirin Therapy

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Quality of Evidence and Strength of Recommendation</th>
</tr>
</thead>
<tbody>
<tr>
<td>A clinician should recommend aspirin therapy for patients diagnosed with T2DM with established ASCVD and consider aspirin therapy for others where the benefits outweighs the risk in primary prevention.</td>
<td>Quality of Evidence: High Strength of Recommendation: Strong</td>
</tr>
</tbody>
</table>

**Benefits:**
Patients with established ASCVD are at high risk for recurrent events, and aspirin therapy for secondary prevention has been shown to reduce the rate of future events to a clinically meaningful degree. As T2DM is an independent risk factor for ASCVD, patients with T2DM might be expected to benefit from aspirin therapy even before they manifest evidence of ASCVD.

**Harms:**
Aspirin therapy could increase the risk of clinically significant bleeding and is also associated with medication cost.

**Benefits-Harms Assessment:**
The substantial reduction in recurrent ASCVD events with aspirin therapy in secondary prevention will outweigh the risk of bleeding for patients with established ASCVD and no contraindications to aspirin use. In patients with T2DM where aspirin is considered for primary prevention, while the risk of clinically significant bleeding is low, it is still likely increased relative to no therapy. At this time, it is unclear whether adding aspirin therapy to other standard therapy for CV risk factors adds net benefit in patients with T2DM who do not have established ASCVD.

**Relevant Resources:**
Rosiak, 2013; Macchia, 2012; Soejima, 2012; Valentine, 2012; Antithrombotic Trialists’ (ATT) Collaboration, 2009; Belch, 2008; Ogawa, 2008; Campbell, 2007; Pignone, 2006

**Supplemental Information**
Patients with T2DM are at a significantly increased risk for development of heart disease (American Diabetes Association, 2014). Recent trials of aspirin use in diabetes have shown less benefit than older trials for primary prevention, perhaps due to better background A1c, blood pressure, and low-density lipoprotein control and lower smoking rates in recent trials (Rosiak, 2013; Macchia, 2012; Belch, 2008; Ogawa, 2008).

Regular use of ibuprofen may undermine aspirin's antiplatelet effects; patients taking both medications regularly should take immediate-release aspirin at least 30 minutes prior to taking ibuprofen or wait at least eight hours after ingestion of ibuprofen.

### 8. Treatment Goals Not Met

If patients are having difficulty achieving treatment goals, consider the following:
- Modification of treatment goals
- Evaluate for potential contributing issues such as adherence, depression and obstructive sleep apnea
9. Ongoing Management

Components of ongoing management for successful T2DM care should include the following:

- Regular follow-up with the health care team (via office visit, e-visit, telephone, labs, etc.) should be scheduled yearly. More frequent visits may be necessary if treatment goals are not achieved.

- Patients starting or having a major change in their treatment program (such as initiating insulin therapy) may need to be in contact with their care clinician as often as daily until glucose control is achieved, the risk of hypoglycemia is low, and the patient is competent to conduct the treatment program and should ideally not be delayed greater than one week.

- Perform a targeted history and physical yearly on all patients, with particular attention to the feet, cardiovascular system and blood pressure.

**Targeted annual history and targeted physical exam:**

- Results of self-monitoring blood glucose – validate results at least once a year (e.g., check patient's glucose meter against an office random capillary glucose)

- Adjustments by the patient of the therapeutic regimen

- Frequency, causes and severity of both hyperglycemia and hypoglycemia

- Problems with adherence to therapeutic regimen

- Symptoms suggesting development or progression of the complications of diabetes

- Current prescribed medications, over-the-counter medications, dietary supplements and alternative therapies

- Documentation of eye care specialist exam results

- Alcohol/drug use patterns

- Annually screen for microalbuminuria

- Assessment for symptoms of depression

- Weight, body mass index

- Blood pressure – all patients with diabetic nephropathy should be on either an ACE inhibitor or ARB

- Cardiovascular – evaluation of preexisting problems

- Feet (nails, web spaces, calluses, ulcers, structural deformities, protective sensation and shoes)

- At each encounter, ask if the patient has experienced symptoms of hypoglycemia or low blood glucose, review and educate the patient on appropriate recognition, prevention and management. If the patient has a history of severe hypoglycemia (assistance of another person was needed to treat a low glucose) or has developed hypoglycemia unawareness, evaluate the treatment goals for appropriate safety.
• All patients with diabetic nephropathy should be on either an ACE inhibitor or ARB unless contraindicated. Consider early nephrology consultation for patients with macroalbuminuria and/or Cr above 1.5 mg/dL.

• Aggressively control hypertension, dyslipidemia, obesity and protein restriction in all patients with nephropathy.

Specialist dilated eye exam

A dilated eye examination for diabetic eye disease performed by an ophthalmologist or optometrist is recommended annually for patients with T2DM (American Diabetes Association, 2014). Less frequent exams (every two to three years) may be considered in the setting of a normal eye exam. The role of fundus photography is still being considered but doesn't replace a comprehensive exam.

Retinopathy

Prevalence of retinopathy is related to the duration of diabetes mellitus. After 20 years of T2DM, more than 60% of patients have some degree of retinopathy (Fong, 2004). Diabetic retinopathy is estimated to be the most frequent cause of new cases of blindness among adults ages 20 to 74 years.

Up to 21% of patients with T2DM are found to have retinopathy at the time of diagnosis of diabetes mellitus (Fong, 2004). Generally, retinopathy progresses from mild background abnormalities to preproliferative retinopathy to proliferative retinopathy.

Poor glucose control is associated with progression of retinopathy. High blood pressure is a risk factor for the development of macular edema and is associated with the development of proliferative retinopathy (Fong, 2004).

Screening for diabetic retinopathy saves vision at a relatively low cost. In fact, screening costs may be less than the costs of disability payments for those who become blind. Laser photocoagulation surgery is effective in preventing visual loss in diabetic retinopathy. Studies have shown that retinal examinations by clinicians who are not eye care specialists are not reliable in detecting retinopathy (Fong, 2004; American College of Physicians, 1992; ETDRS Research Group, 1991; Klein, 1987; ETDRS Research Group, 1985; Klein, 1984; Diabetic Retinopathy Study Research Group, The, 1981).

Renal assessment and nephrology

Urinary albumin excretion should be tested annually by a microalbuminuria method. There is racial/ethnic variability with regard to the prevalence of end-stage renal disease, with Native Americans, Latinos (especially Mexican Americans) and African Americans having higher rates than non-Hispanic whites with T2DM (American Diabetes Association, 2004b). If albuminuria is above normal, serum creatinine should be measured (American Diabetes Association, 2004b; Bennett, 1995; Nelson, 1991).

Screening to detect microalbuminuria

Measurement of the albumin-to-creatinine ratio in a random, spot collection. Consider early nephrology consultation for patients with macroalbuminuria and/or Cr > 1.5 mg/dL. Aggressive control of hypertension, dyslipidemia, obesity and protein restriction is recommended in all patients with nephropathy.

Several factors can artificially increase the levels of albumin in the urine and should be avoided at the time of the urine collection. These include blood in the urine, prolonged heavy exercise, fever, congestive heart failure, uncontrolled diabetes, severe hypertension, urinary tract infection and vaginal fluid contamination of specimen.

If two out of three screening microalbuminuria tests are positive, the individual has microalbuminuria, and interventions should be considered. A negative finding should be followed annually; a positive finding should...
be followed periodically, for example annually, to see if the interventions are effective in diminishing the albuminuria (Hannah, 1999; Mogensen, 1996; Bennett, 1995; National Institutes of Health, 1993).

Nephropathy

In T2DM, albuminuria may be present at the time of diagnosis in about 10% of patients, and another 10% later develop it. Progression to renal failure is less certain in type 2 patients than in type 1 patients and appears to be modulated by genetic and other factors.

Patients with clinical nephropathy almost always have retinopathy and coronary artery disease.

Numerous interventions are appropriate at different stages of renal function in order to prevent or slow the progression of renal disease and associated cardiovascular disease, and include (American Diabetes Association, 2004b):

- Glucose control – Improved glucose control at any stage of renal function reduces renal disease progression.
- ACE inhibitor or ARB should be used in all non-pregnant patients with micro or macroalbuminuria. For patients with T2DM, ACE inhibitors or ARBs can reduce progression of macrovascular complications (Lewis, 2001; Heart Outcomes Prevention Evaluation Study Investigators, The, 2000). Within one week of initiation, check for elevations in potassium and creatinine levels.
- Measure serum creatinine at least annually and more often based on stage of chronic kidney disease (CKD).
- Hypertension control – An ACE inhibitor or ARB should be the initial agent of choice. Current JNC and NKF/DOQI recommendations call for treatment of blood pressure to < 130/80 in patients with CKD. However, no single, adequately powered intent-to-treat randomized control trial has shown a benefit of this blood pressure goal in CKD (Arguedas, 2013; Appel, 2010; Lewis, 2010). Hence, the recommendation for lower blood pressure goals in all patients with CKD is based on expert opinion and not fully supported by available prospective clinical trials. Determining whether therapy should specifically be titrated to goals lower than < 140/90 mgHg for specific subgroups of CKD patients (e.g., those with moderate proteinuria) should be considered on an individual patient basis, based on clinical judgment and patient preference.

- Cardiovascular risk factor intervention – Dyslipidemia is often present with microalbuminuria and should be treated aggressively. Dyslipidemia may be an independent risk factor for progression of renal disease. Smoking is associated with the onset and progression of microalbuminuria.
- Restriction of dietary protein has been shown to slow progression of overt nephropathy (macroalbuminuria), and there may be some benefit in dietary protein reduction in microalbuminuric patients. In these circumstances, protein intake should be reduced to the adult recommended daily allowance of 0.8-1.0 g/kg body weight per day with microalbuminuria present, and 0.8 gm/kg body weight per day with macroalbuminuria present (American Diabetes Association, 2014).

Treatment for microalbuminuria includes aggressive blood pressure control with ACE or ARB use as first-line therapy, glycemic control, and aggressive cardiovascular risk factor screening and management.

Strongly consider referral to nephrology any patients with a creatinine greater than 1.5 mg, or nephrotic range proteinuria (greater than 3 gm/24 hour).

Patients with a creatinine clearance of less than 30 mL/min should be referred to nephrology for discussions of future options and to enhance the ability to receive a future transplant. These patients also have significant enough renal impairment that they also benefit from more intensive nutritional interventions and proper management of anemia and bone disease (American Diabetes Association, 2004b; Karter, 2002; Lewis,
Neuropathy

Peripheral neuropathy is difficult to prevent and treat. Most patients with T2DM and peripheral neuropathy have few symptoms. All patients found to have neuropathy should see a foot care specialist for preventive measures aimed at reducing the incidence of diabetic foot complications.

Good glycemic control should be the first control of symptomatic neuropathy.

**Comprehensive foot exam with risk assessment**

A foot exam should include assessment for the following risk factor for complications:

- Loss of protective sensation. Protective sensation can be assessed using either a 5.07 Semmes-Weinstein monofilament for light touch or by testing vibration using a 128-Hz tuning fork at the dorsum of the interphalangeal joint of the great toe, or both. Patients with reduced or absent sensation with either of these tests should be educated about their risk and the need for proper foot care to prevent foot complications. See Appendix C, "Using a Semmes-Weinstein Monofilament to Screen the Diabetic Foot for Peripheral Sensory Neuropathy," and Appendix D, "Using a Tuning Fork to Screen the Diabetic Foot for Peripheral Neuropathy."

- Peripheral vascular disease (absent pedal pulse, history of claudication or ischemic skin changes)

- Structural deformities (bunion, hammertoes, Charcot deformity, limited joint mobility or prior amputation)

- Skin disorders (nail deformity, callus, fissure, tinea or ulceration)

- Footwear (excessively worn, ill-fitting or inappropriate shoes)

- Medications can improve quality of life in patients with painful neuropathy

**Peripheral Vascular Disease**

Peripheral arterial disease is commonly associated with diabetes (American Diabetes Association, 2003). As many as 36% of patients with diabetes have lower-extremity peripheral arterial disease based on lower-extremity blood pressure readings. However, a typical history of intermittent claudication or an absent peripheral pulse is less commonly noted.

Initial screening for peripheral arterial disease should include asking about claudication and assessment of pedal pulses. Consider obtaining ankle-brachial index if clinically indicated.

Peripheral vascular disease in combination with peripheral neuropathy places patients with diabetes at increased risk for non-traumatic amputations of the lower extremity. Peripheral vascular disease may be slowed by smoking cessation and treatment of hypertension and dyslipidemia.

Aggressive daily foot care, inspection of the feet at every office visit for diabetes mellitus, early treatment of foot infections, treatment of callus, use of moisturizing lotion and proper footwear may forestall problems, including amputation. Vascular surgery may also prevent amputation in some patients with established severe peripheral vascular disease (American Diabetes Association, 2003).

Proper high-risk foot management is necessary to prevent ulceration and amputation. Consider referral of patients with claudication and/or absent pedal pulses to vascular surgery.

See Appendix B, "Treatment of Diabetic Nephropathy."
Cardiovascular and Cerebrovascular Complication Assessment

- History of cardiovascular symptoms such as chest pain, vascular claudication, TIA
- Cardiac and carotid exams
- Screening for coronary heart disease
- Evaluate cardiovascular status before advising increased intensity of exercise (American Diabetes Association, 2004c; Sigal, 2004).

Cardiovascular and Cerebrovascular Disease

Treatment includes control of cardiovascular risk factors (hypertension, dyslipidemia and smoking cessation) and aspirin use. Consider referring patients with known coronary artery disease to cardiology and patients with known carotid disease to a specialist.

Heart failure is also common in patients with diabetes. Metformin may be used in stable congestive heart failure if renal function is normal.

Close monitoring of potassium and renal function is necessary especially if patients have concomitant chronic kidney disease as the common use of diuretics, ACE/ARBs and aldosterone antagonists in these patients may cause hyperkalemia and worsening renal function. Thiazolidinediones should be avoided in patients with congestive heart failure.

For patients with T2DM, thiazide diuretics in the treatment of hypertension can reduce cardiovascular events, particularly heart failure (Wing, 2003; ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group, The, 2002).

Special Considerations

- Hepatitis B vaccine should be administered to unvaccinated adults with diabetes who are < 60 years of age. It may be administered to unvaccinated adults with diabetes who are ≥ 60 years of age.
- Influenza vaccine every year
- Pneumococcal vaccine – repeat the vaccination once after age 65 if the initial vaccination was given prior to 65. Consider repeating the immunization for those at risk of losing immunity after five years including nephrotic syndrome, chronic renal disease and other immunocompromised states.

For further information, see the ICSI Immunizations guideline.
The Aims and Measures section is intended to provide guideline users with a menu of measures for multiple purposes, which may include the following:

- population health improvement measures,
- quality improvement measures for delivery systems,
- measures from regulatory organizations such as Joint Commission,
- measures that are currently required for public reporting,
- measures that are part of Center for Medicare Services Physician Quality Reporting initiative,
- other measures from local and national organizations aimed at measuring population health and improvement of care delivery.

This section provides resources, strategies and measurement for use in closing the gap between current clinical practice and the recommendations set forth in the guideline.

The subdivisions of this section are:

- Aims and Measures
- Implementation Tools and Resources
Aims and Measures

Note: a multifactorial intervention targeting hyperglycemia and cardiovascular risk factors in individuals with diabetes is most effective. Both individual measures of diabetes care, as well as comprehensive measures of performance on broader sets of measures, are recommended. A randomized controlled trial has shown a 50% reduction in major cardiovascular events through a multifactorial intervention targeting hyperglycemia, hypertension, dyslipidemia, microalbuminuria, aspirin and ACE inhibitor use in individuals with microalbuminuria (Gaede, 2003).

Goals for A1c, low-density lipoprotein and other diabetes measures should be personalized, and lower goals for A1c and low-density lipoprotein than those included here in the priority aims and measures may be clinically justified in some adults with T2DM. However, efforts to achieve A1c below 7% may increase risk of mortality, weight gain, hypoglycemia and other adverse effects in many patients with T2DM. Therefore, the aims and measures listed here are selected carefully in the interests of patient safety.

Outcome Measures

1. **Diabetes Optimal Care:** Increase the percentage of patients ages 18-75 years with T2DM mellitus who are optimally managed (individual components and composite measure):

   Measures for accomplishing this aim:
   
   Percentage of patients with T2DM mellitus ages 18-75 years old who achieve any or all of the following:
   
   a. Percentage of patients with HbA1c ≤ 8%.
   b. Percentage of patients with blood pressure most recent measurement less than 140/90 mmHg.
   c. Percentage of patients who are tobacco free.
   d. Percentage of patients with established ASCVD and documented daily aspirin use (unless contraindicated).
   e. Percentage of patients ages 40-75 years with T2DM with untreated LDL > 70 mg/dL who are prescribed statin therapy.
   f. Percentage of patients with all of the above.

2. **Management of T2DM in high-risk patients (Trial measure):** Decrease the percentage of adult patients ages 18-75 with T2DM mellitus with poorly controlled glucose and cardiovascular risk factors (individual components and composite measure):

   Measures for accomplishing this aim:
   
   a. Percentage of patients with T2DM mellitus with HbA1c > 9%.
   b. Percentage of patients with T2DM mellitus with ASCVD and not on statin.
   c. Percentage of patients with T2DM and established ASCVD who do not have documentation of daily aspirin use (exclude patients for whom aspirin is contraindicated).
   d. Percentage of patients with T2DM mellitus with blood pressure measurement greater than 160/100 mmHg.
   e. Percentage of patients who are current smoker.
   f. Percentage of patients with any of the above (a-e).

   Note about trial measure: This measure is intended for internal quality improvement use to measure prevalence of patients with type 2 diabetes whose glucose and cardiovascular factors are poorly controlled.
3. Lifestyle modification and nutrition therapy – increase the percentage of patients ages 18-75 years newly diagnosed with T2DM who are advised about lifestyle modification and nutrition therapy.

Measure for accomplishing this aim:

a. Percentage of newly diagnosed patients who are advised about lifestyle modification and nutrition therapy within one year of diagnosis.

4. Medication Management – increase the percentage of patients with T2DM who are on appropriate medication management.

Measures for accomplishing this aim:

a. Percentage of patients ages 40-75 years with untreated LDL > 70 mg/dL who are prescribed statin therapy.

b. Percentage of patients with established ASCVD with documented aspirin use (unless contraindicated).
Measurement Specifications

Measurement #1 a, b, c, d, e, f: Diabetes Optimal Care

Measurement Description
Percentage of patients with T2DM ages 18-75 years old who achieve any or all of the following:

a. Percentage of patients with HgbA1c < 8%.
b. Percentage of patients with blood pressure most recent measurement less than 140/90 mmHg.
c. Percentage of patients who are tobacco free.
d. Percentage of patients with established ASCVD with documented daily aspirin use (unless contraindicated)
e. Percentage of patients ages 40-75 years and T2DM with untreated LDL > 70 mg/dL who are prescribed statin therapy.
f. Percentage of patients with all of the above.

Population Definition
Patients ages 18-75 years old with T2DM.

Data of Interest
\[
\frac{\text{# of patients who achieve any or all of the following control criteria}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

Numerator and Denominator Definitions

Numerator:

a. Number of patients with HgbA1c < 8%.
b. Number patients with most recent blood pressure measurement less than 140/90 mmHg.
c. Number of patients who are tobacco free.
d. Number of patients with established ASCVD with documented daily aspirin use (unless contraindicated).
e. Number of patients ages 40-75 years with type 2 diabetes and untreated LDL > 70 mg/dL who are prescribed statin therapy.
f. Number of patients with all of the above.

Denominator:

a. Number of patients ages 18-75 years old who have T2DM.
b. Number of patients ages 18-75 years old who have T2DM.
c. Number of patients ages 18-75 years old who have T2DM.
d. Number of patients ages 18-75 years old who have T2DM and established ASCVD.
e. Number of patients ages 40-75 years old who have T2DM and untreated LDL > 70 mg/dL.
f. Number of patients ages 18-75 years old who have T2DM.
Method/Source of Data Collection

Data should be collected from EMR for all patient visits in the past 12 months.

Notes

This is an outcome measure, and improvement is noted as an increase in the rate. This measure should be calculated as both an individual components met and a composite (all components met at the same time) measure.

Goals for A1c, low-density lipoprotein and other diabetes measures should be personalized, and lower goals for A1c and low-density lipoprotein than those included here in the priority aims and measures may be clinically justified in some adults with T2DM. However, efforts to achieve A1c below 7% may increase risk of mortality, weight gain, hypoglycemia and other adverse effects in many patients with T2DM. Therefore, the aims and measures listed here are selected carefully in the interests of patient safety.

Return to Table of Contents
Measurement #2a
Management of T2DM in high-risk patients (Trial Measure)

Measurement Description
Percentage of patients with T2DM with HbAlc > 9%.

Population Definition
Patients ages 18-75 years old with T2DM.

Data of Interest
\[
\frac{\text{# of patients with HbA1c > 9}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

Numerator and Denominator Definitions
Numerator: Number of patients with HbA1c > 9%.
Denominator: Number of patients ages 18-75 years old who have T2DM.

Method/Source of Data Collection
Data should be collected from EMR for all patient visits in the past 12 months.

Notes
This is a process measure, and improvement is noted as a decrease in the rate. The purpose of this measure is to decrease the percentage of adult patients ages 18-75 with T2DM with poorly controlled glucose and cardiovascular risk factors (clinical strategies that target high-risk populations may be more viable with limited resources).

Return to Table of Contents
Measurement #2b

Measurement Description
Percentage of patients with T2DM with ASCVD and not on a statin.

Population Definition
Patients ages 18-75 years old with T2DM.

Data of Interest
\[
\frac{\text{# of patients with ASCVD and not on a statin}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

Numerator and Denominator Definitions
Numerator: Number of patients with ASCVD and not on a statin.
Denominator: Number of patients ages 18-75 years old who have T2DM.

Method/Source of Data Collection
Data should be collected from EMR for all patient visits in the past 12 months.

Notes
This is a process measure, and improvement is noted as a decrease in the rate. The purpose of this measure is to decrease the percentage of adult patients ages 18-75 with T2DM with poorly controlled glucose and cardiovascular risk factors (clinical strategies that target high-risk populations may be more viable with limited resources).

Return to Table of Contents
Measurement #2c

Measurement Description
Percentage of patients with T2DM and established ASCVD who do not have documentation of daily aspirin use (exclude patients for whom aspirin is contraindicated).

Population Definition
Patients ages 18-75 years old with T2DM.

Data of Interest
# of patients with established ASCVD and no documentation of daily aspirin use (unless contraindicated)
# of patients ages 18-75 years old with T2DM

Numerator and Denominator Definitions
Numerator: Number of patients with established ASCVD who do not have documentation of daily aspirin use (exclude patients for whom aspirin is contraindicated).
Denominator: Number of patients ages 18-75 years old who have T2DM.

Method/Source of Data Collection
Data should be collected from EMR for all patient visits in the past 12 months.

Notes
This is a process measure, and improvement is noted as a decrease in the rate. The purpose of this measure is to decrease the percentage of adult patients ages 18-75 with T2DM with poorly controlled glucose and cardiovascular risk factors (clinical strategies that target high-risk populations may be more viable with limited resources).

Return to Table of Contents
Measurement #2d

Measurement Description
Percentage of patients with T2DM with blood pressure greater than 160/100 mm/Hg.

Population Definition
Patients ages 18-75 years old with T2DM.

Data of Interest
\[
\frac{\text{# of patients with BP > 160/100 mmHg}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

Numerator and Denominator Definitions
Numerator: Number of patients with blood pressure measurement greater than 160/100 mmHg.
Denominator: Number of patients ages 18-75 years old who have T2DM.

Method/Source of Data Collection
Data should be collected from EMR for all patient visits in the past 12 months.

Notes
This is a process measure, and improvement is noted as a decrease in the rate. The purpose of this measure is to decrease the percentage of adult patients ages 18-75 with T2DM with poorly controlled glucose and cardiovascular risk factors (clinical strategies that target high-risk populations may be more viable with limited resources).

Return to Table of Contents
**Measurement #2e**

**Measurement Description**
Percentage of patients who currently smoke.

**Population Definition**
Patients ages 18-75 years old with T2DM.

**Data of Interest**
\[
\frac{\text{# of patients who currently smoke}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

**Numerator and Denominator Definitions**
- **Numerator:** Number of patients who currently smoke.
- **Denominator:** Number of patients ages 18-75 years old who have T2DM.

**Method/Source of Data Collection**
Data should be collected from EMR for all patient visits in the past 12 months.

**Notes**
This is a process measure, and improvement is noted as a decrease in the rate. The purpose of this measure is to decrease the percentage of adult patients ages 18-75 with T2DM with poorly controlled glucose and cardiovascular risk factors (clinical strategies that target high-risk populations may be more viable with limited resources).

*Return to Table of Contents*
Measurement #2f

Measurement Description
Percentage of patients with T2DM with any of the following (2a-2e) (composite measure).

Population Definition
Patients ages 18-75 years old with T2DM.

Data of Interest
\[
\frac{\text{# of patients with any of the following (2a-2e)}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

Numerator and Denominator Definitions
Numerator: Number of patients with any of the following (2a-2e).
Denominator: Number of patients ages 18-75 years old who have T2DM.

Method/Source of Data Collection
Data should be collected from EMR for all patient visits in the past 12 months.

Notes
This is a process measure, and improvement is noted as a decrease in the rate. The purpose of this measure is to decrease the percentage of adult patients ages 18-75 with T2DM with poorly controlled glucose and cardiovascular risk factors (clinical strategies that target high-risk populations may be more viable with limited resources).

Return to Table of Contents
Measurement #3a

Measurement Description
Percentage of newly diagnosed patients who are advised about lifestyle modification and nutrition therapy within one year of diagnosis.

Population Definition
Patients ages 18-75 years old with T2DM.

Data of Interest
\[
\frac{\text{# of patients who are advised about lifestyle modification and nutrition therapy within one year of diagnosis}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

Numerator and Denominator Definitions
Numerator: Number of patients who are advised about lifestyle modification and nutrition therapy within one year of diagnosis.
Denominator: Number of patients ages 18-75 years old who have T2DM.

Method/Source of Data Collection
Data should be collected from EMR for all patient visits in the past 12 months.

Notes
This is a process measure, and improvement is noted as an increase in the rate.

Return to Table of Contents
Measurement #4a

Measurement Description
Percentage of patients ages 40-75 with untreated LDL > 70 mg/dL who are prescribed statin therapy.

Population Definition
Patients ages 40-75 years old with T2DM and untreated LDL > 70 mg/dL.

Data of Interest

\[
\frac{\text{# of patients who are prescribed statin therapy}}{\text{# of patients ages 40-75 years old with T2DM and untreated LDL > 70 mg/dL}}
\]

Numerator and Denominator Definitions
Numerator: Number of patients who are prescribed statin therapy.
Denominator: Number of patients ages 40-75 years old who have T2DM and untreated LDL > 70 mg/dL.

Method/Source of Data Collection
Data should be collected from EMR for all patient visits in the past 12 months.

Notes
This is a process measure, and improvement is noted as an increase in the rate.

Return to Table of Contents
**Measurement #4b**

**Measurement Description**
Percentage of patients with established ASCVD with documented aspirin use (unless contraindicated).

**Population Definition**
Patients ages 18-75 years old with T2DM.

**Data of Interest**

\[
\frac{\text{# of patients with established ASCVD with documented aspirin use (unless contraindicated)}}{\text{# of patients ages 18-75 years old with T2DM}}
\]

**Numerator and Denominator Definitions**

Numerator: Number of patients with established ASCVD with documented aspirin use (unless contraindicated).

Denominator: Number of patients ages 18-75 years old who have T2DM.

**Method/Source of Data Collection**
Data should be collected from EMR for all patient visits in the past 12 months.

**Notes**
This is a process measure, and improvement is noted as an increase in the rate.

Implementation Tools and Resources

Criteria for Selecting Resources

The following tools and resources specific to the topic of the guideline were selected by the work group. Each item was reviewed thoroughly by at least one work group member. It is expected that users of these tools will establish the proper copyright prior to his/her use. The types of criteria the work group used are:

- The content supports the clinical and the implementation recommendations.
- Where possible, the content is supported by evidence-based research.
- The author, source and revision dates for the content is included where possible.
- The content is clear about potential biases and when appropriate conflicts of interests and/or disclaimers are noted where appropriate.

Appendix A – Order Set: Subcutaneous Insulin Management

This order set will cover the orders of subcutaneous insulin management. This order will not include admission orders or other specific orders for the patient’s condition outside of insulin management. The target population is hospitalized adults who require subcutaneous insulin for their clinical care and does not include orders for critical care patients.

Patient Information (Two are required.)

- Last Name: ______________________
- First Name: ______________________
- Date of Birth: __ / __
- Patient’s Age: _____
- ID #: ____________________________

Legend:
- Open boxes are orders that a clinician will need to order by checking the box.
- Pre-checked boxes are those orders with strong supporting evidence and/or regulatory requirements that require documentation if not done.

Admitting/Attending Information

Admit unit: _______________________

Attending physician: _______________________

How to contact: _______________________

Diagnosis

Admitting diagnosis: _______________________

Secondary diagnosis: _______________________

Nursing

Blood glucose level goals
- Preprandial = 90-140 mg/dL
- Postprandial less than 180 mg/dL
- Other: ______ mg/dL

Blood glucose monitoring frequency (Select all that apply.)
- _______ minutes before meals
- Bedtime
- 0200-0300 (all times listed in 24-hour time)
- Nothing by mouth, total parenteral nutrition (TPN), or continuous enteral feeding: monitor based on insulin dosing schedule every:
  - 4 hours
  - 6 hours

- Other _______________________

Return to Table of Contents
Dosing schedule

- Basal insulin (check one)
  - Glargine insulin _______ units subcutaneous at ____________ hours (24-hour time)
  - Glargine insulin twice daily:
    Units subcutaneous at _______ hours (24-hour time) AND
    Units subcutaneous at _______ hours (24-hour time)
  - Detemir insulin _______ units subcutaneous daily at ____________ hours (24-hour time)
  - Detemir insulin twice daily:
    _______ units subcutaneous at ____________ hours (24-hour time) AND
    _______ units subcutaneous at ____________ hours (24-hour time)
  - NPH insulin _______ units subcutaneous each a.m.
    _______ units subcutaneous each evening meal
    _______ units subcutaneous at bedtime

- Other ___________________________ units subcutaneous every _______ hours (24-hour time)

- Prandial insulin (Do not give if patient is NPO or if preprandial glucose is less than 60 mg/dL.)
  - Lispro insulin _______ units subcutaneous at ____________ hours (24-hour time)
  - Aspart insulin _______ units subcutaneous at ____________ hours (24-hour time)
  - Glulisine insulin _______ units subcutaneous at ____________ hours (24-hour time)

- Bedtime (If blood glucose is less than 200 mg/dL, do not give correction dose; if greater than 200 mg/dL, give 50% of correction dose. Patients receiving corticosteroids may be at greater risk for nocturnal hypoglycemia, so caution is required in giving insulin correction dose at bedtime for these patients.)

Return to Table of Contents
Corrective dose insulin for patients who have nothing by mouth, on total parenteral nutrition or on continuous enteral feeding (to be given in addition to basal insulin)

Check one:
- [ ] Regular insulin – check blood glucose every 6 hours and administer insulin dose based on correction schedule
- [ ] Lispro insulin – check blood glucose every 4 hours and administer insulin dose based on correction schedule
- [ ] Aspart insulin – check blood glucose every 4 hours and administer insulin dose based on correction schedule
- [ ] Glulisine insulin – check blood glucose every 4 hours and administer insulin dose based on correction schedule
- [ ] Other – check blood glucose every ___ hours and administer insulin dose based on correction schedule
- [ ] Other diabetic medications: __________________________________________________________

Transition from intravenous insulin to subcutaneous insulin:
- [ ] Administer initial dose of subcutaneous basal insulin two hours prior to discontinuation of intravenous insulin infusion. Record blood glucose prior to administering basal insulin dose.
- [ ] Initial dose of subcutaneous basal insulin
  - [ ] Glargine insulin _______ units at _______ hours (24-hour time)
  - [ ] Detemir insulin _______ units at _______ hours (24-hour time)
  - [ ] NPH insulin _______ units at _______ hours (24-hour time)
- [ ] Discontinue intravenous insulin infusion at _______ hours (24-hour time). Record blood glucose at time intravenous insulin infusion is discontinued.
- [ ] Subsequent basal, prandial and correction insulin doses in accordance with orders above

Diet
- [ ] Consistent carbohydrate (CHO) meal plan
- [ ] Bedtime snack
- [ ] Other ________________________________

Laboratory/Diagnostic Testing
- [ ] A1c (if A1c from past 2-3 months or unknown)
- [ ] Electrolytes, blood urea nitrogen (BUN), creatinine
- [ ] Alanine amino transaminase (ALT)
- [ ] Aspartate transaminase (AST)
- [ ] Hypoglycemia protocol

Discharge/Transition Planning – Patient Education
- [ ] Diabetes clinical nurse specialist consult (reason for consult): ____________________________
- [ ] Diabetes education consult inpatient survival skills (reason for consult): __________________
- [ ] Diabetes education consult outpatient (reason for consult): ______________________________
- [ ] Nutrition services consult (reason for consult): ________________________________

Appendix B – Treatment of Diabetic Nephropathy

Screen patients with diabetic nephropathy

Dipstick test urine sample
• Positive microalbumin reaction

Semiquantitative immunoassay test
• Positive correlates well with > 20 mg albumin/24 hr

Quantitative tests
• Albumin/creatinine ratio on random urine sample (easiest for patients)
• 24-hour urine collection
• Time urine collection (4-hour or overnight)
• Positive is ≥ 30 mg/24 hr or 30 > mg/g Cr

Repeat screen annually

Positive for microalbumin?

Verify all positive tests
• Use 2 additional quantitative screening tests
• Perform verification tests over next 2-3 months

2 of 3 tests positive for urine albumin?

Microalbuminuria: Perform periodic 24-hr creatinine clearance and urine protein tests to assess renal function and treatment success
• Blood pressure control
• ACE inhibitor use
• Glycemic control
• Lipid/CV risk factor control
• Consider referral to nephrology specialist

Macroalbuminuria: Suspect overt nephropathy
• Referral to nephrology specialist

False positives for urine albumin may occur secondary to:
• UTI
• Fever
• Blood in urine
• Heart failure
• Extreme hypertension
• Vaginal fluid contamination
• Uncontrolled blood glucose
• Prolonged exercise

Definition for microalbuminuria and macroalbuminuria
• Microalbuminuria: ≥ 30 mg/24 hr or ≥ 30 mg/g Cr
• Macroalbuminuria: > 300 mg/24 hr or > 300 mg/g Cr
Appendix C – Using a Semmes-Weinstein Monofilament to Screen the Diabetic Foot for Peripheral Sensory Neuropathy

1) Show the monofilament to the patient and touch it to his/her arm to demonstrate that it does not hurt.

2) Use the Semmes-Weinstein 5.07/10 gram monofilament to test sensation at the indicated sites on each foot*. Avoid applying the monofilament to calluses, ulcers, or scars. A foot exam is not reimbursed by Medicare without monofilament sensation testing in four locations.

3) Hold the monofilament perpendicular to the skin and touch it to the skin using a smooth motion with sufficient force to cause the filament to bend. The test should take about 1-1/2 seconds at each site.

4) Ask the patient to respond "yes" when the filament is felt. If the patient does not respond when you touch a given site on the foot, continue on to another site in a random sequence. When you have completed testing all sites on the foot, retest any site(s) where the patient did not feel the filament.

5) The results of the monofilament testing should be documented in the medical record**. PATIENTS WHO CANNOT FEEL THE MONOFILAMENT AT ANY SITE SHOULD BE CONSIDERED TO BE INSENSATE AND AT INCREASED RISK FOR ULCERATION AND AMPUTATION.

*Testing at the first and fifth metatarsal heads is sufficient. This combination of sites has been shown to detect the insensate foot with reasonable sensitivity (80%) and specificity (86%). Testing the great toes may be of added benefit.

**Chart documentation is required for the American Diabetes Association – Clinician Recognition Program. An annual diabetic foot examination is also one of the eight diabetes quality improvement project (DQIP) measures adopted by the National Committee for Quality Assurance (NCQA) and the Health Care Financing Administration.
Appendix D – Using a Tuning Fork to Screen the Diabetic Foot for Peripheral Neuropathy

Peripheral neuropathy can be assessed by vibration perception threshold using a 128-cps tuning fork. The assessment is abnormal if the patient cannot sense the vibration of the tuning fork when it is pressed against the foot.

1. To initiate tuning fork vibration, tap the fork to the ball of your hand.

2. Apply the tuning fork on the wrist of the patient. This is a preliminary step to ensure the patient knows what sensation they should expect.

3. Next, apply the tuning fork, perpendicularly with constant pressure, on a bony part on the dorsal side of the distal phalanx of the first toe. The patient's eyes should be closed during testing.

4. Ask the patient if he/she feels the vibration. If he/she responds "yes," ask him/her to inform you when the vibration stops. An abnormal result occurs when the patient informs you that the vibration stops before you can feel the vibration end.

5. Perform the test three times.

6. The test is positive if the patient correctly answers at least two out of three applications, and negative ("at risk for ulceration") with two out of three incorrect answers.
Appendix E – Sample of Hypoglycemia Protocol

Sample Hypoglycemia Protocol

| For glucose less than 70 mg/dL, patient is not alert/unresponsive | Give 1 amp of D50 IV  
If no IV access, administer 1 mg glucagon IM  
May repeat glucagon x1  
Call covering physician |
<table>
<thead>
<tr>
<th></th>
<th></th>

</thead>
<tbody>
<tr>
<td>For glucose 60-70 mg/dL, but patient is NOT symptomatic</td>
<td>No treatment; Recheck glucose in 30 min. if more than 30 min. until next meal</td>
</tr>
</tbody>
</table>
| For glucose 60-70 mg/dL, patient is symptomatic but alert | Give 15 gm of carbohydrates. Choose one of the following:  
• 4 oz. of any juice by mouth  
• 15 gm of glucose gel  
• 3 glucose tablets |
| For glucose 45-59 mg/dL, patient is alert | Give 20 gm of carbohydrates. Choose one of the following:  
• 6 oz. of any juice by mouth  
• 20 gm of glucose gel  
• 4 glucose tablets  
*If nothing by mouth, give 1/2 amp of D50 IV* |
| For glucose less than 45 mg/dL, patient is alert | Give 30 gm of carbohydrates. Choose one of the following:  
• 8 oz. of any juice by mouth  
• 30 gm of glucose gel  
• 6 glucose tablets  
*If nothing by mouth, give 1/2 amp of D50 IV* |

Adapted from Hennepin County Medical Center, Minneapolis, MN

Recheck blood glucose every 15 minutes and repeat until blood glucose is greater than 60 mg/dL without symptoms, or blood glucose is greater than 70 mg/dL if symptoms persist. Once the patient is stable, recheck glucose after 60 minutes.

*Return to Table of Contents*
ICSI has long had a policy of transparency in declaring potential conflicting and competing interests of all individuals who participate in the development, revision and approval of ICSI guidelines and protocols.

In 2010, the ICSI Conflict of Interest Review Committee was established by the Board of Directors to review all disclosures and make recommendations to the board when steps should be taken to mitigate potential conflicts of interest, including recommendations regarding removal of work group members. This committee has adopted the Institute of Medicine Conflict of Interest standards as outlined in the report, Clinical Practice Guidelines We Can Trust (2011).

Where there are work group members with identified potential conflicts, these are disclosed and discussed at the initial work group meeting. These members are expected to recuse themselves from related discussions or authorship of related recommendations, as directed by the Conflict of Interest committee or requested by the work group.

The complete ICSI Policy regarding Conflicts of Interest is available at http://bit.ly/ICSICOI.

**Funding Source**

The Institute for Clinical Systems Improvement provided the funding for this guideline revision. ICSI is a not-for-profit, quality improvement organization based in Bloomington, Minnesota. ICSI's work is funded by the annual dues of the member medical groups and five sponsoring health plans in Minnesota and Wisconsin. Individuals on the work group are not paid by ICSI but are supported by his/her medical group for this work.

ICSI facilitates and coordinates the guideline development and revision process. ICSI, member medical groups and sponsoring health plans review and provide feedback but do not have editorial control over the work group. All recommendations are based on the work group's independent evaluation of the evidence.

Return to Table of Contents
The ICSI Patient Advisory Council meets regularly to respond to any scientific document review requests put forth by ICSI facilitators and work groups. Patient advisors who serve on the council consistently share his/her experiences and perspectives in either a comprehensive or partial review of a document, and engaging in discussion and answering questions. In alignment with the Institute of Medicine's triple aims, ICSI and its member groups are committed to improving the patient experience when developing health care recommendations.

All ICSI documents are available for review during the revision process by member medical groups and sponsors. In addition, all members commit to reviewing specific documents each year. This comprehensive review provides information to the work group for such issues as content update, improving clarity of recommendations, implementation suggestions and more. The specific reviewer comments and the work group responses are available to ICSI members at http://www.icsi.org.

The next revision will be no later than August 2019.
ICSI Document Development and Revision Process

Overview
Since 1993, the Institute for Clinical Systems Improvement (ICSI) has developed more than 60 evidence-based health care documents that support best practices for the prevention, diagnosis, treatment or management of a given symptom, disease or condition for patients.

Audience and Intended Use
The information contained in this ICSI Health Care Guideline is intended primarily for health professionals and other expert audiences.

This ICSI Health Care Guideline should not be construed as medical advice or medical opinion related to any specific facts or circumstances. Patients and families are urged to consult a health care professional regarding his/her own situation and any specific medical questions they may have. In addition, they should seek assistance from a health care professional in interpreting this ICSI Health Care Guideline and applying it in his/her individual case.

This ICSI Health Care Guideline is designed to assist clinicians by providing an analytical framework for the evaluation and treatment of patients, and is not intended either to replace a clinician's judgment or to establish a protocol for all patients with a particular condition.

Document Development and Revision Process
The development process is based on a number of long-proven approaches and is continually being revised based on changing community standards. The ICSI staff, in consultation with the work group and a medical librarian, conduct a literature search to identify systematic reviews, randomized clinical trials, meta-analysis, other guidelines, regulatory statements and other pertinent literature. This literature is evaluated based on the GRADE methodology by work group members. When needed, an outside methodologist is consulted.

The work group uses this information to develop or revise clinical flows and algorithms, write recommendations, and identify gaps in the literature. The work group gives consideration to the importance of many issues as they develop the guideline. These considerations include the systems of care in our community and how resources vary, the balance between benefits and harms of interventions, patient and community values, the autonomy of clinicians and patients and more. All decisions made by the work group are done using a consensus process.

ICSI's medical group members and sponsors review each guideline as part of the revision process. They provide comment on the scientific content, recommendations, implementation strategies and barriers to implementation. This feedback is used by and responded to by the work group as part of his/her revision work. Final review and approval of the guideline is done by ICSI's Committee on Evidence-Based Practice. This committee is made up of practicing clinicians and nurses, drawn from ICSI member medical groups.

Implementation Recommendations and Measures
These are provided to assist medical groups and others to implement the recommendations in the guidelines. Where possible, implementation strategies are included which have been formally evaluated and tested. Measures are included which may be used for quality improvement as well as for outcome reporting. When available, regulatory or publicly reported measures are included.

Document Revision Cycle
Scientific documents are revised every 12-24 months as indicated by changes in clinical practice and literature. Each ICSI staff monitors major peer-reviewed journals every month for the guidelines for which they are responsible. Work group members are also asked to provide any pertinent literature through check-ins with the work group mid-cycle and annually to determine if there have been changes in the evidence significant enough to warrant document revision earlier than scheduled. This process complements the exhaustive literature search that is done on the subject prior to development of the first version of a guideline.
